Some surgeons have advocated immediate suture of the gall-bladder after removing a stone (*ideal cholecystotomy*). I believe this is never advisable when the stones are active for harm, because small calculi may be in the ducts and minute fragments of stone are often left in the bladder, and the drainage will remove them. Drainage also relieves the diseased condition of the gall-ducts and bladder. In Kocher's 31 operations by this method, gall-stones re-formed in 3 cases. Further, the operation with immediate suture is decidedly more dangerous when infection exists. The Mayos only employ it in latent cases of gall-stone disease when the existence of stones is discovered during the performance of an abdominal operation.

It is advised by some that the operation of cholecystostomy be performed in *two stages*. First, the bladder is exposed and sutured to the parietal peritoneum. When adhesion takes place, the gall-bladder can be opened without risk of infecting the general peritoneal surface. Riedel advocates operation in two stages, and so did Christian Fenger in certain cases. The two-stage operation is objectionable because it does not permit of satisfactory exploration of the ducts. The *biliary fistula* which is left by cholecystostomy usually closes spontaneously, but may not. If it does not close and the secretion is pure mucus, it is evident that the cystic duct is absolutely blocked and cholecystectomy should be performed.

If the secretion from a persistent fistula is bile and if the common duct is not obstructed, separate the edges of the gall-bladder opening from the parietal peritoneum, endeavoring to avoid entering the abdominal cavity, and close the fistula with Lembert or Halsted sutures. If the secretion is bile and the common duct is obstructed permanently, perform *cholecystenterostomy*. If the secretion does not contain bile and the cystic duct is blocked, remove the gall-bladder. At the end of 1907 Hans Kehr placed his mortality at 2 per cent. ("Jour. de Chir.," Oct., 1908). The report of St. Mary's Hospital, Rochester (the Mayo clinic), for 1912 shows 426 cholecystostomies, with 3 deaths.

The McArthur Drip.—In 1909 Lewis L. McArthur suggested using a biliary fistula as a means for introducing fluid or food into the duodenum. He

proved that if a tube draining bile from the gall-bladder is connected to an irrigator containing salt solution (elevated not more than 20 inches and giving a rate of flow not over 5 or 6 drops a second), there will be a continuous flow of fluid into the duodenum without any discomfort to the patient (McArthur, in "New York Med. Jour.," Jan. 27, 1912). Matas has improved the method by introducing into the duodenum at the time of operation and by way of the common duct a ureteral catheter, through which food, fluid, or medicine can be at any time carried into the duodenum (Rudolph Matas, in "New Orleans Med. and Surg. Jour.," Oct., 1911). The method is used in many cases of obstructive jaundice (after removal of the obstruction). The salt solution relieves thirst, removes toxins, and stimulates the kidneys. It relieves post-operative vomiting, favors intestinal peristalsis, combats flatulent distention, and causes movements of the bowels. Matas points out that liquid food

Fig. 726.—Showing method of holding parts while approximating a Murphy button in cholecystenterostomy.

and medicines (strychnin, castor oil, Hunyadi water, etc.) can be given by the biliary route. McArthur believes that the method can be used instead of jejunostomy in certain cases of pyloric obstruction and stomach ulceration.

Cholecystenterostomy[1] consists in making an anastomosis between the gall-bladder and intestine, preferably the duodenum, or, if this cannot be done, the jejunum. It is employed in cases of irremovable obstruction of the common duct. It is done chiefly in cases of malignant obstruction. It is not a suitable operation for gall-stones impacted in the common duct, because it does not remove the cause of trouble, infection of the bile-passages may follow, and the fistula is liable to contract. In those rare cases of common duct obstruction from gall-stones, in which the gall-bladder is distended and the patient is desperately ill, it may be done (Robson). In such a case Robson attaches the gall-bladder to the colon because the operation is easier and because he considers it as useful as the attachment to the duo-

[1] The operation was suggested by Nussbaum, but was first performed by Winiwarter in 1882 ("A Manual of Operative Surgery," by Sir Frederick Treves).

denum. Cholecystenterostomy can be done most rapidly and successfully by means of a small Murphy button. Before the gall-bladder is incised it is aspirated. Murphy's operation is shown in Fig. 726, and is similar in performance to intestinal anastomosis. I believe that Brentano is right and that it is best to do posterior cholecystenterostomy, bringing the jejunum through an opening made in the transverse mesocolon.

Cholecystectomy is the extirpation of the gall-bladder. It was first performed by Langenbuch in 1882. Sometimes primary extirpation is performed; at other times cholecystectomy is performed as a secondary operation, cholecystostomy for drainage having been first performed. Its performance may be demanded by the existence of phlegmonous inflammation or gangrene, ulceration, "in chronic cholecystitis from gall-stones where the gall-bladder is shrunken and too small to safely drain, and where the common duct is free from obstruction" (A. W. Mayo Robson), in empyema with greatly damaged walls, in fistula associated with irremediable obstruction of the cystic duct, the common duct being free, in cancer, and in some wounds of the gall-bladder. Objections to the operation are that drainage can only be obtained by putting a tube into the hepatic or the common duct, and that, should renewed drainage be subsequently required, the necessary operation will prove difficult and dangerous (Maurice H. Richardson, "Medical News," May 2, 1903).

After opening the abdomen the gall-bladder is found and is drawn into the wound. If it is distended and tense or if it is thought "to contain infectious fluid" (Lilienthal), it is packed about with iodoform gauze and emptied by an aspirating trocar. "When the walls are very friable, it is even wise to incise and empty the viscus, closing the opening by ligature or clamp before proceeding with the extirpation. The gall-bladder is usually quite a tough organ, and in the majority of cases it may be grasped with an ovarian ring-clamp applied near its fundus, which at the same time closes the aspiration puncture" (Lilienthal, "Annals of Surgery," July, 1904). The peritoneum which covers the gall-bladder must be divided just below the liver, the gall-bladder is dissected from the liver until the cystic duct is reached, the cystic artery is tied and divided, and if the liver ducts are healthy, the cystic duct is ligated with silk and divided, the stump is touched with pure carbolic acid and is covered with a layer of peritoneum fastened by sutures of fine silk. In cases free from infection it is not necessary to drain the bile-ducts. In cases with cholangitis external drainage is necessary, and it is obtained by incising the hepatic duct and inserting a drainage-tube, or, better, by leaving the stump of the cystic duct open. The report of St. Mary's Hospital, Rochester, Minnesota (the Mayo clinic), shows 255 cases of cholecystectomy with 5 deaths. Howard Lilienthal (Ibid.) reported 42 cases with 1 death. Hans Kehr's mortality at the end of 1907 was 3.6 per cent. ("Jour. de Chir.," Oct., 1908).

Removal of the Mucous Membrane of the Gall-bladder.—Mayo has suggested the removal of the fundus and of all the mucous membrane of the gall-bladder as an occasional substitute for cholecystectomy. By this operation we are enabled to drain the cystic duct and through it the hepatic ducts. A serious objection to the operation is that, as glands pass from the mucous coat to and through the muscular coat, it is impossible absolutely to remove the mucous membrane of the gall-bladder alone (Emil Reis).

Drainage of the Hepatic Duct.—This operation is employed for certain hepatic infections. It was first performed by Cabot in 1892. If the cystic duct is dilated throughout, it may be carried out through that. After opening the gall-bladder a tube is passed through the cystic and into the hepatic duct. It is often done after opening the common duct, a tube being carried up into the hepatic duct. The hepatic duct may be exposed and

opened directly, a tube being carried into it for a short distance and stitched to the edges of the incision in the duct by catgut. The tube should be surrounded by iodoform gauze.

Supraduodenal choledochotomy is the operation of incising the common bile-duct above the duodenum for the removal of a stone. It is also called *choledocholithotomy*. If drainage is used it is *choledochostomy*. It was first performed by Kümmel in 1889. Courvoisier did his first operation in 1890.

Cases upon which this operation is done are often deeply jaundiced and there is grave danger of infection and perhaps of fatal oozing of blood. In 1 of my cases this happened. The patient was laboring under stones in the common duct, associated with cancer of the head of the pancreas. In every case in which operation is contemplated for obstruction of the bile-ducts take the coagulation time of the blood. Normal coagulation time (taken by Wright's coagulometer) is from three to six minutes. Prolongation to seven or eight minutes calls for pre-operative treatment to hasten coagulability. If jaundice exists, it is customary to endeavor to prevent hemorrhage by employing Robson's plan: Give by the mouth from 30 to 60 gr. of chlorid of calcium three times a day during the twenty-four or forty-eight hours preceding operation, and 60 gr. by enema three times a day for the forty-eight hours following operation. I have followed this course in a number of cases, but am not convinced of its value. Instead of this method we may follow the plan of giving thyroid extract (5 gr. three times a day) for several days preceding operation.

The plan I now pursue I am certain does reduce the coagulation time distinctly. I give an injection of horse serum the day before operation and another the morning of the operation.

When ready to operate, a sand-bag should be placed under the lower ribs. This will bring the liver at least 2 inches nearer to the abdominal wound. The abdominal incision must be longer than that employed for cholecystostomy. The pylorus and stomach are drawn to the left, the colon and omentum are drawn downward, and the liver and ribs are lifted strongly upward. Gauze packs are inserted.

"The operator should now, after having separated adhesions, have a good view of the common duct within the free border of the lesser omentum, and on inserting his left index-finger into the foramen of Winslow, or on grasping the duct between the index-finger and thumb, he can, without difficulty, bring the duct well within reach, the concretion making a distinct projection."[1] A longitudinal incision is made, the stone is removed, and a probe is introduced into the duct to determine whether other stones are present.

Stones in the second and third portions of the duct are often missed and the second portion of the duodenum should always be palpated with the utmost care. If the lowermost stone removed from the common duct is faceted, we should always search most carefully to find a concretion which is lower still (F. Gregory Connell, "Annals of Surgery," April, 1908).

If a calculus is found in the lower part of the common duct, the surgeon tries to push it up so that he may reach it. This can usually be accomplished. Failing to push the stone up into reach, some try and force it into the duodenum. This attempt will sometimes, but seldom, succeed. If it does not succeed, the surgeon must perform a transduodenal, or a retroduodenal operation. Only in cases so shocked that prolonged operation is impossible is it proper to do cholecystostomy or cholecystenterostomy. If either of these palliative operations is performed a radical operation must be done later.

Many surgeons suture the incision in the duct. This procedure is rendered easier by the use of Halsted's hammer, which draws the duct toward the surface and keeps it under control (Fig. 727).

[1] A. W. Mayo-Robson's "Treatise on Diseases of the Gall-bladder and Bile-ducts."

Interrupted sutures of fine catgut are used. The muscular and serous coats may be included in each suture, and over this layer Lembert or Halsted sutures are applied. A drainage-tube is inserted and a piece of iodoform gauze is placed upon the suture line, the other end being brought out of the abdominal wound. This precaution is taken because leakage may occur. If it is found impossible to suture the wound in the duct, the operation then becomes a *choledochostomy* (although this term is usually used only when the incised duct is stitched to the abdominal wall). The surgeon carries a glass tube down to the opening and surrounds it with iodoform gauze, or inserts a rubber drainage-tube into the opening and carries it up toward the hepatic duct, or makes an incision into the right loin after the plan of Rutherford Morison, and carries a tube into the right kidney pouch, which is the most dependent part of the peritoneal cavity when the patient is recumbent. Personally I always drain the duct, when I have opened it for stone, carrying the tube up toward the hepatic duct. The same reasons which cause us to drain the gall-bladder after removing stones should influence us in this case.

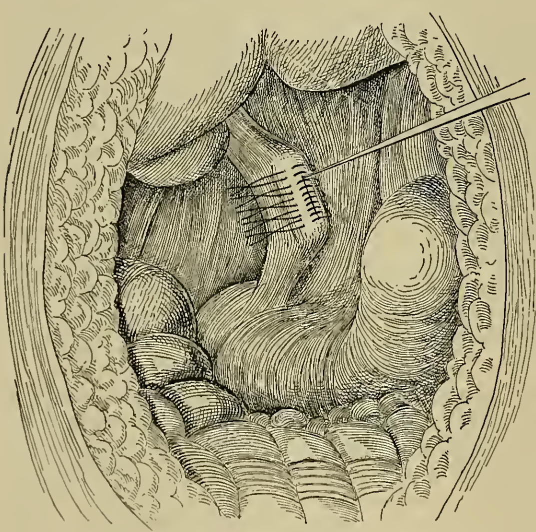

Fig. 727.—Suture of duct over Halsted's hammer.

Robson ("Lancet," April 22, 1902) has performed the operation of choledochotomy 60 times. In 10 cases of stone in the common duct he manipulated the stone back into the gall-bladder and removed it through an incision in that viscus by means of a scoop. The above maneuver is impossible unless the cystic duct is dilated. In 30 cases he crushed the stones between his finger and thumb, but this is only possible when the stones are soft, and it has the objection that it may leave fragments. If a stone is lodged in the common duct and cannot be manipulated back into the gall-bladder, choledochotomy should be performed. Robson's mortality in 60 cases of choledochotomy was 16.6 per cent. Since 1900 his mortality has been 7.1 per cent. Before that it was 23.8 per cent. Kehr's mortality is 4.1 per cent. During 1912 the Mayos performed choledochotomy 96 times, with 5 deaths ("Report of St. Mary's Hospital for 1912").

Hepaticotomy.—By this term we mean the opening of the hepatic duct. If the opening is drained the procedure is, in reality, *hepaticostomy*, although this term is seldom used to designate it. Hepaticotomy is performed for stone in the hepatic duct. The operation was first performed by Kocher in 1889. There were 7 cases on record in 1903 (Delagenière, in "Bull. et Mém. de Chir. de Paris," No. 10, 1903).

Duodenocholedochotomy (McBurney's Operation; the Transduodenal Route).—This operation is seldom necessary. In the more than 2000 operations performed by the Mayos on the gall-bladder and ducts, it was only required in 4 cases. I have never performed it. In 1891 McBurney proposed the method for the removal of gall-stones impacted near the papilla

("Annals of Surgery," Oct., 1898). McBurney's original suggestion was to open the duodenum, dilate or incise the papilla, remove the stone, and suture the duodenum. The duodenum must be mobilized so that it may be lifted into the wound. If the stone is located in the diverticulum of Vater, it may, in some few cases, be removed by simply stretching the opening of the duct with forceps (Collins's method). If this is not possible, the opening in the papilla may be enlarged by cutting or the duodenal mucous membrane over the stone may be incised (McBurney's plan). When the stone is not impacted at the outlet, but is lodged a little higher up, and when dense adhesions render access by the ordinary supraduodenal route difficult or impossible, the anterior wall of the duodenum may be opened longitudinally, the posterior wall of the duodenum and the common duct incised over the stone, the stone removed, the duodenum and common duct sutured together (Kocher's method, or *internal choledochoduodenostomy*), and the anterior wall of the duodenum closed. (See Charles Otto Thienhaus, in "Annals of Surgery," Dec., 1902.) After finding and removing a stone by the transduodenal route we must make a careful search to see that no stones are left before closing the duodenal incision. Robson opposes the transduodenal route and says he has abandoned it because of the danger of sepsis. Thienhaus (Ibid.) opposes this view of Robson and shows that in 29 operations by the transduodenal route there were but 2 deaths.

Connell ("Annals of Surgery," Jan., 1908) has collected 77 cases in which stones were removed by the transduodenal route. There were 10 deaths. In 2 of these cases duodenal fistula preceded death.

Retroduodenal Choledochotomy.—In this operation the second portion of the common duct is incised back of the duodenum without opening the gut. That this may be done the duodenum must first be drawn toward the midline of the body, and this can be done only by "mobilizing" the duodenum, incising the posterior layer of the parietal peritoneum 1 inch to the right of the descending portion of the duodenum. After freeing the gut and retroperitoneal structures the duodenum becomes sufficiently free to lift toward the left with a rotation. We thus expose the posterior aspect of the duodenum, the head of the pancreas, and the common duct.

The duct is opened, the stone removed, the duct sutured, and a drain inserted.

This operation has been successfully performed by a number of surgeons, but there is a great objection to it. In nearly all cases the common bile-duct passes *through* the pancreas rather than back of it. Büngner found this to be the case in 55 out of 58 dissections ("Gray's Anatomy," Seventeenth American edition, p. 1352). Hence, incision of the common duct in this situation means in nearly all cases incision of the pancreas and all the grave dangers of leaking of pancreatic fluid. The transduodenal operation is a much better procedure.

Total Splenectomy.—This operation is performed for wounds and rupture of the spleen, tumors, cysts, floating spleen, and non-leukemic splenic hypertrophy. Twisting of the pedicle of an ectopic or wandering spleen calls imperatively for operation. It should not be performed for hypertrophy in leukemia.

Vedova (quoted in "Practical Medicine Series," 1913, vol. ii) collected 134 cases of splenectomy for traumatic rupture of the spleen. There were 40 deaths. He adds these to Berger's 60 cases, with 25 deaths. This makes a total of 194 cases, with 65 deaths (33.5 per cent.).

In view of the bone-marrow changes in splenomyelogenous leukemia, we cannot hope to cure a patient by removing the spleen. In a leukemic patient the operation has a very high mortality from shock and hemorrhage. Geo. Ben Johnston ("Annals of Surgery," Jan., 1908) has collected 49 splenectomies in leukemia with only 6 operative recoveries (a mortality of 87.7 per cent.).

One of the 6 cases lived eight months, 1 lived four years, and it is claimed that 1 was cured.

Splenectomy has been performed for malarial hypertrophy (ague-cake). The operation has been advocated on the theory that by removing the spleen we get rid of the lurking place of the malarial parasites, but they also lurk in the bone-marrow and in the capillaries of the liver. The operation should not be performed for malarial spleen unless the organ is movable, unless it greatly interferes with the patient's comfort or occupation, or unless we fear rupture, and then, if it is done, it is for the movability, the discomfort, or the danger of rupture, and not for the malaria. It is to be noted that the operation does not cure the malaria. Johnston ("Annals of Surgery," Jan., 1908) collected 58 splenectomies performed for malarial hypertrophy since 1900. There were 50 recoveries and 8 deaths. To these he adds 3 successful ones of his own, making 61 cases, with 8 deaths (a mortality of 13.1 per cent.).

A number of operations have been done for splenic anemia or its terminal stage, which is known as Banti's disease. Those who believe that the splenic enlargement and anemia result from some underlying condition common to both do not operate. The theory of the operation is that removal of the spleen stops the production of some toxic material which causes anemia and cirrhosis of the liver, in other words, that the splenic disease causes the anemia. There seems ample evidence that splenectomy, if done early, may save the patient. It is useless and highly dangerous to do it after the development of the second stage of Banti's disease. Cushing's case was alive and well eight years after the operation.

Johnston (Ibid.) has collected 61 splenectomies for splenic anemia or Banti's disease. There were 49 recoveries and 12 deaths, a mortality of 19.5 per cent. I have performed splenectomy twice for Banti's disease, with one recovery and one death.

Johnston (Ibid.) notes 12 splenectomies for sarcoma of the spleen, with 9 recoveries. One lived eight and one-half years and died of heart disease; 3 are known to have died from recurrent sarcoma.

It is stated that there are on record 4 splenectomies for cancer. Moynihan doubts the diagnostic accuracy of the three earlier reports. Mary A. Smith records a case of colloid cancer occurring in a woman who had been operated on ten years before for ovarian cyst associated with pseudomyxoma of the peritoneum. The pathologist reported that the growth in the spleen was a metastasis of colloid carcinoma. This patient died seven months after the splenectomy from peritoneal and omental cancer ("Annals of Surg.," Jan., 1908).

In Johnston's table of 708 splenectomies for various causes (Loc. cit.) the mortality is 27.4 per cent. In the cases operated upon from 1900 to 1907 inclusive the mortality is 18.5 per cent.

In order to remove the spleen most operators make an incision from the anterosuperior spine of the ilium to the ribs. I prefer to make an incision below the left costal margin like Kocher's incision on the right side to reach the gall-bladder. This incision can be extended to any necessary degree, and posterior drainage of the pancreas region can emerge from its outer end. Open the peritoneum and divide adhesions between ligatures. If the spleen is adherent to the pancreas, it may be necessary to remove a fragment of the last-named organ. It is a very undesirable thing to have to do, and I lost a case from pancreatic leakage after having done it. Ligate the suspensory ligament and divide it. Bring the spleen well out of the wound. Surround it with gauze pads. Transfix the pedicle with stout silk. Tie it firmly, leaving the ends of the ligature long for a time, and cut through the pedicle beyond the ligature. Ligate the vessels separately with catgut. Cut off the long ends of the silk ligature and drop the pedicle back, unless apprehensive of bleeding, when it may

be fastened to the surface. The wound is closed without drainage, unless the pancreas has been injured, in which case posterior drainage is employed. Traction upon and ligation of the vessels in the pedicle may cause profound shock by injuring the splenic plexus, which is in close relation with the solar plexus (Jordan, in "Lancet," Jan. 22, 1899).

Changes After Splenectomy.—About two weeks after the removal of a normal spleen certain definite changes happen in adults, but not in children. These changes last for several weeks, and are manifested by enlargement of the lymph-glands, pain in and tenderness of bones, blood changes, loss of weight, weakness, thirst, polyuria, abdominal pain, elevation of temperature, and rapid pulse.[1] Tizzoni says that these changes are not obvious in children, because in them compensatory organs act at once, whereas in adults compensatory organs act slowly and with painful effort. Such symptoms are noticed when the spleen is removed because of a wound or a rupture, but rarely after removal of a diseased spleen. It is likely that compensating organs become active when the spleen is diseased, and consequently are in full operation when such a spleen is removed. After partial splenectomy these changes are not noted (Jordan). Changes can be prevented after splenectomy by the administration of tablets of extract of spleen, and red bone-marrow (Ballance), and iron (especially in foods) is of value.

The blood changes after splenectomy consist of diminution in hemoglobin and red blood-cells. The coloring-matter and cells do not become normal for two or three months.

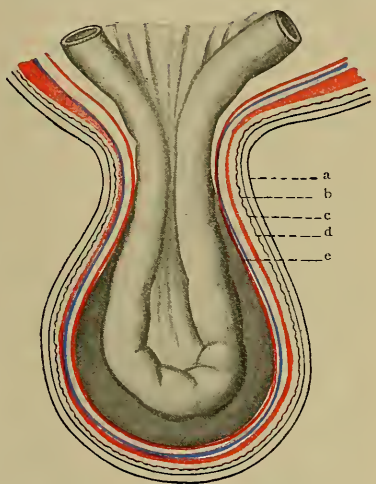

Fig. 728.—A diagrammatic representation of the coverings of a hernia: *a*, The skin; *b*, the superficial fascia; *c*, the muscular layer—*e. g.*, the cremaster muscle in an inguinal hernia; *d*, the transversalis fascia; *c*, *d*, have also been called the fascia propria herniæ; *e*, the peritoneum—*i. e.*, the sac of the hernia (Sultan).

Splenopexy.—This is the operation of anchoring a movable spleen. It should only be used when the spleen is not enlarged and is not diseased. Rydygier in 1895 published the first case, although both Tuffier and Kouwer operated before this date. Sutures should not be passed through the spleen: the structure is so soft that stitches are bound to loosen and the insertion will cause bleeding. A promising method is to create adhesions by the use of iodoform gauze, as is done for movable kidney, and as was done by Kouwer. Some advocate making a pocket outside of the peritoneum and bringing the spleen into this pocket, thus placing it extraperitoneal.

Abdominal Hernia or Rupture.—A hernia is a protrusion of peritoneum liable to contain, containing at times, or permanently containing any viscus or part of a viscus from the abdominal cavity. MacCormac says the term implies that the protruded viscus is covered with integument; hence a protrusion of viscera through a wound does not constitute a hernia. A hernia has three parts—the sac, the sac-contents, and the sac-coverings (Fig. 728). The *sac* is formed of peritoneum. A *congenital sac* is due to developmental defect, and may be in the inguinal region, the femoral region, the umbilical region, the lumbar region, or in the epigastric region. In the epigastric region it is a result of a congenital slit in the transversalis fascia. It used to be stated that femoral hernia was never congenital, but

[1] Ballance, in "Practitioner," April, 1898; H. Martyn Jordan, in "Lancet," Jan. 22, 1898.

Russell and Coley both say that a femoral hernia may have a congenital sac. In 100 necropsies Murray found 20 potential femoral sacs (sacs into which a hernia had not entered). An *acquired sac* is due to intra-abdominal pressure bulging the peritoneal covering of an abdominal ring and converting it into a pouch. The sac comprises a *body*, a *neck*, and a *mouth*. A sac once formed is almost certain to persist, because it adheres by its outer surface to surrounding parts; and hence the sac of a hernia is usually irreducible even when the contents are reducible. The *neck of the sac* is due to the constriction through which the sac passes; it becomes furrowed and folded, and the adhesion of these folds causes thickening and rigidity. Hernia of the bladder or of the cecum may have no sac or but a partial sac. A ventral hernia following an abdominal operation may be without a sac. The *contents of the sac* depend chiefly on the situation, a portion of the ileum being the usual contents. The colon, the stomach, the great omentum, the bladder, and other structures may enter the hernial sac. An *enterocele* contains only intestine; an *epiplocele* contains only omentum; an *entero-epiplocele* contains both omentum and intestine; a *cystocele* contains a portion of the bladder. The *coverings of the sac*, which vary with its situation, will be set forth during the consideration of special forms of hernia. In old hernia the layers are never distinct, fat and muscle waste, tissues adhere, and the skin stretches and atrophies. The sac of an old hernia occasionally becomes tuberculous, and the disease may remain local in the hernial sac or spread to the general peritoneum. Renault tells us that *tuberculosis of a hernia* is made manifest by increase in size, pain on pressure, and loss of body weight.

Causes of Hernia.—Hernia is a common trouble. According to Berger, in 1000 people 4.4 per cent. suffer from hernia. It occurs at all periods of life, and hereditary predisposition sometimes seems to exist. The male sex is three times as liable to hernia as the female sex. That increase of intra-abdominal tension is a common cause in children has been amply demonstrated. (See Hernia in Childhood, page 1158.) Excessive length of the mesentery has been assigned as a cause. In some instances a mass of fat forms (*fat hernia*) and advances before the hernia, and seems to bear a causative relation to it. Lucas-Championnière explains this as follows: When a person begins to take on fat, it is deposited not only under the skin, but also in the omentum, mesentery, and subperitoneal tissues. The semifluid fat is easily influenced by pressure. The deposit of fat within the abdomen lessens the size of that cavity, intra-abdominal pressure is increased, and subperitoneal fat protrudes at any weak spot in the wall. The protruding mass of fat adheres to and makes traction upon the peritoneum, and this membrane is drawn upon to form a sac, and the sac is surrounded by fat. This method of formation is frequently noticed in umbilical herniæ, and occasionally in inguinal herniæ. Any laborious occupation predisposes to rupture. Any condition which weakens the abdominal wall predisposes to rupture (muscular relaxation from ill-health, relaxation of abdominal walls following the termination of pregnancy, the removal of a large tumor or tapping for ascites, and wounds or abscesses of the abdominal wall). The commonly assigned cause is repeated muscular effort which increases intra-abdominal tension (straining at stool, coughing, lifting weights, jumping, the sexual act, and straining during micturition). In 25 per cent. of cases the cause is supposed to have been lifting or carrying a weight (Coley). I am satisfied that in some cases at least the external abdominal ring enlarges before it has been stretched by a descending hernia. Such a condition predisposes to hernia by weakening muscular support of the abdomen. A hernia may appear gradually or suddenly. Berger and Coley state that nearly 70 per cent. of herniæ in adult males appear gradually. The sac of an acquired hernia exists for a longer or shorter time before the hernia

enters it. The sac of a congenital hernia is present at birth. The sac of an acquired hernia forms gradually. A sac may exist for years and yet remain empty. When bowel or omentum enters it from some strain or effort, the parts were long prepared to receive the extruded mass. This extrusion may occur gradually or it may occur suddenly. If it occurs suddenly, the sufferer believes that his hernia was formed then and there, but, as a matter of fact, the extrusion of bowel or omentum and its entrance into the sac were but the last of a long series of antecedent and preparatory changes. Finally, a hernia appears, and often does so during effort. In rare cases traumatism may cause a hernia immediately, no sac existing before the accident. It does so in the inguinal region by stretching or tearing the internal ring, the inguinal canal at once enlarging. Such a condition is a true *traumatic hernia*, traumatism being the sole cause and not simply the exciting cause.

The old and erroneous idea was that a hernia was always formed by tearing of the peritoneum; hence the term *rupture*. This mode of formation is extremely unusual, but occasionally does occur. Coley saw such a case. An ordinary non-traumatic hernia, when the bowel suddenly and for the first time enters the sac, is the seat of some pain, but the pain is not disabling and the lump disappears on recumbency. In many cases the bowel or omentum gradually finds a way into the sac, and in such cases pain is usually trivial and may even be absent. In true traumatic hernia there are violent pain, collapse, vomiting, inability to walk and stand, and the mass does not return to the belly on recumbency, but must be reduced by taxis or operation. True traumatic herniæ may occur anywhere in the abdomen, but are most common in the inguinal region, where they are direct herniæ. (The relation born by accidents to the development of hernia is discussed by Paul Berger, in "Rev. de Chir.," April and May, 1906, and by Wm. B. Coley, in "Internat. Jour. of Surg.," Feb., 1908). All congenital herniæ are due to structural defects. Herniæ are divided clinically into *reducible*, *irreducible*, *incarcerated*, *inflamed*, and *strangulated.*

Reducible Hernia.—In this form of hernia the contents of the sac can be reduced into the abdominal cavity. At a known hernial opening the patient has a smooth enlargement (narrower above than below), which began to grow above and extended downward. A distinct neck can often be felt. In enterocele, straining, lifting, or standing enlarges the mass; the protrusion becomes smaller and may disappear on lying down; cough causes impulse or succussion, the protrusion is elastic, and may be tympanitic on percussion, and on reduction the mass suddenly disappears and there is a gurgling sound. In epiplocele the mass is often irregular and compressible, and feels boggy rather than elastic; muscular effort does not have much influence in enlarging it; impulse on coughing is slight; percussion gives a dull note, and reduction is accomplished gradually and produces no gurgling sound. In entero-epiplocele some parts of the mass are smooth, elastic, and perhaps tympanitic; others are dull on percussion, irregular, and flabby, but the diagnosis of this especial form from the other forms is often uncertain. The victims of reducible hernia complain of some pain on exertion, of dyspepsia, and often of constipation.

When a hernia is beginning to form there is often *premonotory uneasiness;* the patient complains of muscular pain in the lower abdomen, and this condition may exist for weeks or months before it is recognized that a hernia is present. An inguinal hernia can be recognized before it protrudes from the external ring. The tip of the finger is inserted in the ring and the patient is asked to cough. If a hernia has entered the canal, succussion will be detected on coughing. In a healthy man the external ring should admit the tip of the little finger, but not the end of the index-finger. If the end of the index-finger can be made to enter the ring that aperture is dilated, and even if there is no hernia in the canal, in future a hernia will probably descend. In a man, if the

surgeon desires to examine the ring, he inverts the skin of the scrotum over the finger and carries the finger to or in the ring. When the hernia first appears there may be pain, faintness, and some sick stomach, but often there is no pain or any discomfort.

Treatment of Reducible Hernia.—*Palliative Treatment.*—Prevent constipation and forbid sudden strains and violent exercise. If operation is refused or inadvisable, order a truss. The continued employment of a truss in young persons may bring about a cure. The day truss should be applied before rising in the morning and be removed after lying down at night, when a light truss should be substituted. A special truss is applied before bathing. In very fat people there is always trouble in adjusting a truss. A femoral hernia is more difficult to keep reduced than an inguinal hernia. In a hernia in which the gut is replaceable, but a portion of omentum is irreducible, it is difficult to maintain reduction of the gut with a truss, and an operation should be performed. In an oblique inguinal hernia the pad of the truss fits over the internal abdominal ring; in a direct inguinal hernia, over the external abdominal ring; in a femoral hernia, over the femoral ring at the level of Gimbernat's ligament. MacCormac's method of measuring for a truss is as follows: In either inguinal or femoral hernia start the tape from the *lower part* of the hernial opening, carry it up to the anterior superior iliac spine of the same side, then take it around the body, 1 inch below the crest of the ilium, to the other anterior superior iliac spine, and then to the upper part of the hernial opening.[1] A well-fitting truss will keep the hernia up even when the patient sits in a position to relax the abdominal walls and coughs and strains. A truss is always uncomfortable at first, but a person usually becomes accustomed to it. It should be kept scrupulously clean, and borated talc powder should be dusted upon the skin under the pad at least once a day. A truss which does not keep the hernia up or which causes pain does harm. Too strong a spring tends to enlarge the hernial orifice, and thus aggravates the case. Even after an apparent cure with a truss the instrument must be worn for a long time.

Radical treatment of reducible and of non-strangulated hernia seeks to obtain cure by plugging the mouth of the sac or by obliterating the canal of descent. Radical operations should be performed when a strangulated hernia is operated upon, in ordinary cases of reducible hernia, particularly if a truss is very painful or does not keep the bowel up, in most cases of irreducible hernia, and in any case of hernia in which there are occasional attacks of obstruction. It was formerly believed that a cure would fail if the subject was under three years of age, but Coley and others have proved that it is a very successful operation in childhood. It is rarely recommended under the age of four, because in two-thirds of the cases a truss will cure very young subjects. It is strongly advised in children after the age of four when a truss has failed, when there is irreducible omentum, or when there is a reducible hydrocele which prevents the truss from holding (Wm. B. Coley, in "Annals of Surgery," June, 1903). The radical operation is almost without danger in properly selected cases, and is one of the most successful of surgical procedures. We are justified in doing the operation upon an individual under fifty years of age and free from complications, purely to relieve him or her from the annoyance of wearing a truss. If, however, a patient is sixty years of age or over and a truss keeps the hernia up satisfactorily, the operation should not be performed unless it is demanded by some complication. Organic diseases of the heart, lungs, and kidneys are contra-indications. Enormous herniæ (Figs. 729 and 730) are unfavorable for operation. Restoration is difficult or impossible, the forcible handling produces much shock, and recurrence is to be expected.

[1] Treves's "Manual of Surgery," "Hernia."

opened directly, a tube being carried into it for a short distance and stitched to the edges of the incision in the duct by catgut. The tube should be surrounded by iodoform gauze.

Supraduodenal choledochotomy is the operation of incising the common bile-duct above the duodenum for the removal of a stone. It is also called *choledocholithotomy*. If drainage is used it is *choledochostomy*. It was first performed by Kümmel in 1889. Courvoisier did his first operation in 1890.

Cases upon which this operation is done are often deeply jaundiced and there is grave danger of infection and perhaps of fatal oozing of blood. In 1 of my cases this happened. The patient was laboring under stones in the common duct, associated with cancer of the head of the pancreas. In every case in which operation is contemplated for obstruction of the bile-ducts take the coagulation time of the blood. Normal coagulation time (taken by Wright's coagulometer) is from three to six minutes. Prolongation to seven or eight minutes calls for pre-operative treatment to hasten coagulability. If jaundice exists, it is customary to endeavor to prevent hemorrhage by employing Robson's plan: Give by the mouth from 30 to 60 gr. of chlorid of calcium three times a day during the twenty-four or forty-eight hours preceding operation, and 60 gr. by enema three times a day for the forty-eight hours following operation. I have followed this course in a number of cases, but am not convinced of its value. Instead of this method we may follow the plan of giving thyroid extract (5 gr. three times a day) for several days preceding operation.

The plan I now pursue I am certain does reduce the coagulation time distinctly. I give an injection of horse serum the day before operation and another the morning of the operation.

When ready to operate, a sand-bag should be placed under the lower ribs. This will bring the liver at least 2 inches nearer to the abdominal wound. The abdominal incision must be longer than that employed for cholecystostomy. The pylorus and stomach are drawn to the left, the colon and omentum are drawn downward, and the liver and ribs are lifted strongly upward. Gauze packs are inserted.

"The operator should now, after having separated adhesions, have a good view of the common duct within the free border of the lesser omentum, and on inserting his left index-finger into the foramen of Winslow, or on grasping the duct between the index-finger and thumb, he can, without difficulty, bring the duct well within reach, the concretion making a distinct projection."[1] A longitudinal incision is made, the stone is removed, and a probe is introduced into the duct to determine whether other stones are present.

Stones in the second and third portions of the duct are often missed and the second portion of the duodenum should always be palpated with the utmost care. If the lowermost stone removed from the common duct is faceted, we should always search most carefully to find a concretion which is lower still (F. Gregory Connell, "Annals of Surgery," April, 1908).

If a calculus is found in the lower part of the common duct, the surgeon tries to push it up so that he may reach it. This can usually be accomplished. Failing to push the stone up into reach, some try and force it into the duodenum. This attempt will sometimes, but seldom, succeed. If it does not succeed, the surgeon must perform a transduodenal, or a retroduodenal operation. Only in cases so shocked that prolonged operation is impossible is it proper to do cholecystostomy or cholecystenterostomy. If either of these palliative operations is performed a radical operation must be done later.

Many surgeons suture the incision in the duct. This procedure is rendered easier by the use of Halsted's hammer, which draws the duct toward the surface and keeps it under control (Fig. 727).

[1] A. W. Mayo-Robson's "Treatise on Diseases of the Gall-bladder and Bile-ducts."

Interrupted sutures of fine catgut are used. The muscular and serous coats may be included in each suture, and over this layer Lembert or Halsted sutures are applied. A drainage-tube is inserted and a piece of iodoform gauze is placed upon the suture line, the other end being brought out of the abdominal wound. This precaution is taken because leakage may occur. If it is found impossible to suture the wound in the duct, the operation then becomes a *choledochostomy* (although this term is usually used only when the incised duct is stitched to the abdominal wall). The surgeon carries a glass tube down to the opening and surrounds it with iodoform gauze, or inserts a rubber drainage-tube into the opening and carries it up toward the hepatic duct, or makes an incision into the right loin after the plan of Rutherford Morison, and carries a tube into the right kidney pouch, which is the most dependent part of the peritoneal cavity when the patient is recumbent. Personally I always drain the duct, when I have opened it for stone, carrying the tube up toward the hepatic duct. The same reasons which cause us to drain the gall-bladder after removing stones should influence us in this case.

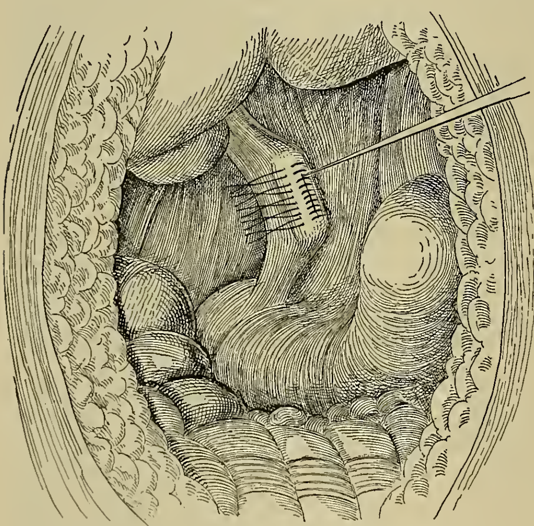

Fig. 727.—Suture of duct over Halsted's hammer.

Robson ("Lancet," April 22, 1902) has performed the operation of choledochotomy 60 times. In 10 cases of stone in the common duct he manipulated the stone back into the gall-bladder and removed it through an incision in that viscus by means of a scoop. The above maneuver is impossible unless the cystic duct is dilated. In 30 cases he crushed the stones between his finger and thumb, but this is only possible when the stones are soft, and it has the objection that it may leave fragments. If a stone is lodged in the common duct and cannot be manipulated back into the gall-bladder, choledochotomy should be performed. Robson's mortality in 60 cases of choledochotomy was 16.6 per cent. Since 1900 his mortality has been 7.1 per cent. Before that it was 23.8 per cent. Kehr's mortality is 4.1 per cent. During 1912 the Mayos performed choledochotomy 96 times, with 5 deaths ("Report of St. Mary's Hospital for 1912").

Hepaticotomy.—By this term we mean the opening of the hepatic duct. If the opening is drained the procedure is, in reality, *hepaticostomy*, although this term is seldom used to designate it. Hepaticotomy is performed for stone in the hepatic duct. The operation was first performed by Kocher in 1889. There were 7 cases on record in 1903 (Delagenière, in "Bull. et Mém. de Chir. de Paris," No. 10, 1903).

Duodenocholedochotomy (McBurney's Operation; the Transduodenal Route).—This operation is seldom necessary. In the more than 2000 operations performed by the Mayos on the gall-bladder and ducts, it was only required in 4 cases. I have never performed it. In 1891 McBurney proposed the method for the removal of gall-stones impacted near the papilla

("Annals of Surgery," Oct., 1898). McBurney's original suggestion was to open the duodenum, dilate or incise the papilla, remove the stone, and suture the duodenum. The duodenum must be mobilized so that it may be lifted into the wound. If the stone is located in the diverticulum of Vater, it may, in some few cases, be removed by simply stretching the opening of the duct with forceps (Collins's method). If this is not possible, the opening in the papilla may be enlarged by cutting or the duodenal mucous membrane over the stone may be incised (McBurney's plan). When the stone is not impacted at the outlet, but is lodged a little higher up, and when dense adhesions render access by the ordinary supraduodenal route difficult or impossible, the anterior wall of the duodenum may be opened longitudinally, the posterior wall of the duodenum and the common duct incised over the stone, the stone removed, the duodenum and common duct sutured together (Kocher's method, or *internal choledochoduodenostomy*), and the anterior wall of the duodenum closed. (See Charles Otto Thienhaus, in "Annals of Surgery," Dec., 1902.) After finding and removing a stone by the transduodenal route we must make a careful search to see that no stones are left before closing the duodenal incision. Robson opposes the transduodenal route and says he has abandoned it because of the danger of sepsis. Thienhaus (Ibid.) opposes this view of Robson and shows that in 29 operations by the transduodenal route there were but 2 deaths.

Connell ("Annals of Surgery," Jan., 1908) has collected 77 cases in which stones were removed by the transduodenal route. There were 10 deaths. In 2 of these cases duodenal fistula preceded death.

Retroduodenal Choledochotomy.—In this operation the second portion of the common duct is incised back of the duodenum without opening the gut. That this may be done the duodenum must first be drawn toward the midline of the body, and this can be done only by "mobilizing" the duodenum, incising the posterior layer of the parietal peritoneum 1 inch to the right of the descending portion of the duodenum. After freeing the gut and retroperitoneal structures the duodenum becomes sufficiently free to lift toward the left with a rotation. We thus expose the posterior aspect of the duodenum, the head of the pancreas, and the common duct.

The duct is opened, the stone removed, the duct sutured, and a drain inserted.

This operation has been successfully performed by a number of surgeons, but there is a great objection to it. In nearly all cases the common bile-duct passes *through* the pancreas rather than back of it. Büngner found this to be the case in 55 out of 58 dissections ("Gray's Anatomy," Seventeenth American edition, p. 1352). Hence, incision of the common duct in this situation means in nearly all cases incision of the pancreas and all the grave dangers of leaking of pancreatic fluid. The transduodenal operation is a much better procedure.

Total Splenectomy.—This operation is performed for wounds and rupture of the spleen, tumors, cysts, floating spleen, and non-leukemic splenic hypertrophy. Twisting of the pedicle of an ectopic or wandering spleen calls imperatively for operation. It should not be performed for hypertrophy in leukemia.

Vedova (quoted in "Practical Medicine Series," 1913, vol. ii) collected 134 cases of splenectomy for traumatic rupture of the spleen. There were 40 deaths. He adds these to Berger's 60 cases, with 25 deaths. This makes a total of 194 cases, with 65 deaths (33.5 per cent.).

In view of the bone-marrow changes in splenomyelogenous leukemia, we cannot hope to cure a patient by removing the spleen. In a leukemic patient the operation has a very high mortality from shock and hemorrhage. Geo. Ben Johnston ("Annals of Surgery," Jan., 1908) has collected 49 splenectomies in leukemia with only 6 operative recoveries (a mortality of 87.7 per cent.).

One of the 6 cases lived eight months, 1 lived four years, and it is claimed that 1 was cured.

Splenectomy has been performed for malarial hypertrophy (ague-cake). The operation has been advocated on the theory that by removing the spleen we get rid of the lurking place of the malarial parasites, but they also lurk in the bone-marrow and in the capillaries of the liver. The operation should not be performed for malarial spleen unless the organ is movable, unless it greatly interferes with the patient's comfort or occupation, or unless we fear rupture, and then, if it is done, it is for the movability, the discomfort, or the danger of rupture, and not for the malaria. It is to be noted that the operation does not cure the malaria. Johnston ("Annals of Surgery," Jan., 1908) collected 58 splenectomies performed for malarial hypertrophy since 1900. There were 50 recoveries and 8 deaths. To these he adds 3 successful ones of his own, making 61 cases, with 8 deaths (a mortality of 13.1 per cent.).

A number of operations have been done for splenic anemia or its terminal stage, which is known as Banti's disease. Those who believe that the splenic enlargement and anemia result from some underlying condition common to both do not operate. The theory of the operation is that removal of the spleen stops the production of some toxic material which causes anemia and cirrhosis of the liver, in other words, that the splenic disease causes the anemia. There seems ample evidence that splenectomy, if done early, may save the patient. It is useless and highly dangerous to do it after the development of the second stage of Banti's disease. Cushing's case was alive and well eight years after the operation.

Johnston (Ibid.) has collected 61 splenectomies for splenic anemia or Banti's disease. There were 49 recoveries and 12 deaths, a mortality of 19.5 per cent. I have performed splenectomy twice for Banti's disease, with one recovery and one death.

Johnston (Ibid.) notes 12 splenectomies for sarcoma of the spleen, with 9 recoveries. One lived eight and one-half years and died of heart disease; 3 are known to have died from recurrent sarcoma.

It is stated that there are on record 4 splenectomies for cancer. Moynihan doubts the diagnostic accuracy of the three earlier reports. Mary A. Smith records a case of colloid cancer occurring in a woman who had been operated on ten years before for ovarian cyst associated with pseudomyxoma of the peritoneum. The pathologist reported that the growth in the spleen was a metastasis of colloid carcinoma. This patient died seven months after the splenectomy from peritoneal and omental cancer ("Annals of Surg.," Jan., 1908).

In Johnston's table of 708 splenectomies for various causes (Loc. cit.) the mortality is 27.4 per cent. In the cases operated upon from 1900 to 1907 inclusive the mortality is 18.5 per cent.

In order to remove the spleen most operators make an incision from the anterosuperior spine of the ilium to the ribs. I prefer to make an incision below the left costal margin like Kocher's incision on the right side to reach the gall-bladder. This incision can be extended to any necessary degree, and posterior drainage of the pancreas region can emerge from its outer end. Open the peritoneum and divide adhesions between ligatures. If the spleen is adherent to the pancreas, it may be necessary to remove a fragment of the last-named organ. It is a very undesirable thing to have to do, and I lost a case from pancreatic leakage after having done it. Ligate the suspensory ligament and divide it. Bring the spleen well out of the wound. Surround it with gauze pads. Transfix the pedicle with stout silk. Tie it firmly, leaving the ends of the ligature long for a time, and cut through the pedicle beyond the ligature. Ligate the vessels separately with catgut. Cut off the long ends of the silk ligature and drop the pedicle back, unless apprehensive of bleeding, when it may

be fastened to the surface. The wound is closed without drainage, unless the pancreas has been injured, in which case posterior drainage is employed. Traction upon and ligation of the vessels in the pedicle may cause profound shock by injuring the splenic plexus, which is in close relation with the solar plexus (Jordan, in "Lancet," Jan. 22, 1899).

Changes After Splenectomy.—About two weeks after the removal of a normal spleen certain definite changes happen in adults, but not in children. These changes last for several weeks, and are manifested by enlargement of the lymph-glands, pain in and tenderness of bones, blood changes, loss of weight, weakness, thirst, polyuria, abdominal pain, elevation of temperature, and rapid pulse.[1] Tizzoni says that these changes are not obvious in children, because in them compensatory organs act at once, whereas in adults compensatory organs act slowly and with painful effort. Such symptoms are noticed when the spleen is removed because of a wound or a rupture, but rarely after removal of a diseased spleen. It is likely that compensating organs become active when the spleen is diseased, and consequently are in full operation when such a spleen is removed. After partial splenectomy these changes are not noted (Jordan). Changes can be prevented after splenectomy by the administration of tablets of extract of spleen, and red bone-marrow (Ballance), and iron (especially in foods) is of value.

The blood changes after splenectomy consist of diminution in hemoglobin and red blood-cells. The coloring-matter and cells do not become normal for two or three months.

Splenopexy.—This is the operation of anchoring a movable spleen. It should only be used when the spleen is not enlarged and is not diseased. Rydygier in 1895 published the first case, although both Tuffier and Kouwer operated before this date. Sutures should not be passed through the spleen: the structure is so soft that stitches are bound to loosen and the insertion will cause bleeding. A promising method is to create adhesions by the use of iodoform gauze, as is done for movable kidney, and as was done by Kouwer. Some advocate making a pocket outside of the peritoneum and bringing the spleen into this pocket, thus placing it extraperitoneal.

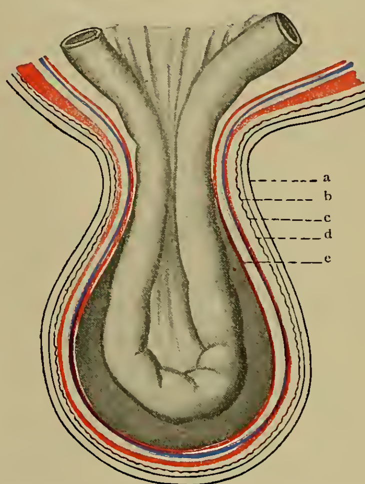

Fig. 728.—A diagrammatic representation of the coverings of a hernia: *a*, The skin; *b*, the superficial fascia; *c*, the muscular layer—*e. g.*, the cremaster muscle in an inguinal hernia; *d*, the transversalis fascia; *c*, *d*, have also been called the fascia propria herniæ; *e*, the peritoneum—*i. e.*, the sac of the hernia (Sultan).

Abdominal Hernia or Rupture.—A hernia is a protrusion of peritoneum liable to contain, containing at times, or permanently containing any viscus or part of a viscus from the abdominal cavity. MacCormac says the term implies that the protruded viscus is covered with integument; hence a protrusion of viscera through a wound does not constitute a hernia. A hernia has three parts—the sac, the sac-contents, and the sac-coverings (Fig. 728). The *sac* is formed of peritoneum. A *congenital sac* is due to developmental defect, and may be in the inguinal region, the femoral region, the umbilical region, the lumbar region, or in the epigastric region. In the epigastric region it is a result of a congenital slit in the transversalis fascia. It used to be stated that femoral hernia was never congenital, but

[1] Ballance, in "Practitioner," April, 1898; H. Martyn Jordan, in "Lancet," Jan. 22, 1898.

Russell and Coley both say that a femoral hernia may have a congenital sac. In 100 necropsies Murray found 20 potential femoral sacs (sacs into which a hernia had not entered). An *acquired sac* is due to intra-abdominal pressure bulging the peritoneal covering of an abdominal ring and converting it into a pouch. The sac comprises a *body*, a *neck*, and a *mouth*. A sac once formed is almost certain to persist, because it adheres by its outer surface to surrounding parts, and hence the sac of a hernia is usually irreducible even when the contents are reducible. The *neck of the sac* is due to the constriction through which the sac passes; it becomes furrowed and folded, and the adhesion of these folds causes thickening and rigidity. Hernia of the bladder or of the cecum may have no sac or but a partial sac. A ventral hernia following an abdominal operation may be without a sac. The *contents of the sac* depend chiefly on the situation, a portion of the ileum being the usual contents. The colon, the stomach, the great omentum, the bladder, and other structures may enter the hernial sac. An *enterocele* contains only intestine; an *epiplocele* contains only omentum; an *entero-epiplocele* contains both omentum and intestine; a *cystocele* contains a portion of the bladder. The *coverings of the sac*, which vary with its situation, will be set forth during the consideration of special forms of hernia. In old hernia the layers are never distinct, fat and muscle waste, tissues adhere, and the skin stretches and atrophies. The sac of an old hernia occasionally becomes tuberculous, and the disease may remain local in the hernial sac or spread to the general peritoneum. Renault tells us that *tuberculosis of a hernia* is made manifest by increase in size, pain on pressure, and loss of body weight.

Causes of Hernia.—Hernia is a common trouble. According to Berger, in 1000 people 4.4 per cent. suffer from hernia. It occurs at all periods of life, and hereditary predisposition sometimes seems to exist. The male sex is three times as liable to hernia as the female sex. That increase of intra-abdominal tension is a common cause in children has been amply demonstrated. (See Hernia in Childhood, page 1158.) Excessive length of the mesentery has been assigned as a cause. In some instances a mass of fat forms (*fat hernia*) and advances before the hernia, and seems to bear a causative relation to it. Lucas-Championnière explains this as follows: When a person begins to take on fat, it is deposited not only under the skin, but also in the omentum, mesentery, and subperitoneal tissues. The semifluid fat is easily influenced by pressure. The deposit of fat within the abdomen lessens the size of that cavity, intra-abdominal pressure is increased, and subperitoneal fat protrudes at any weak spot in the wall. The protruding mass of fat adheres to and makes traction upon the peritoneum, and this membrane is drawn upon to form a sac, and the sac is surrounded by fat. This method of formation is frequently noticed in umbilical herniæ, and occasionally in inguinal herniæ. Any laborious occupation predisposes to rupture. Any condition which weakens the abdominal wall predisposes to rupture (muscular relaxation from ill-health, relaxation of abdominal walls following the termination of pregnancy, the removal of a large tumor or tapping for ascites, and wounds or abscesses of the abdominal wall). The commonly assigned cause is repeated muscular effort which increases intra-abdominal tension (straining at stool, coughing, lifting weights, jumping, the sexual act, and straining during micturition). In 25 per cent. of cases the cause is supposed to have been lifting or carrying a weight (Coley). I am satisfied that in some cases at least the external abdominal ring enlarges before it has been stretched by a descending hernia. Such a condition predisposes to hernia by weakening muscular support of the abdomen. A hernia may appear gradually or suddenly. Berger and Coley state that nearly 70 per cent. of herniæ in adult males appear gradually. The sac of an acquired hernia exists for a longer or shorter time before the hernia

enters it. The sac of a congenital hernia is present at birth. The sac of an acquired hernia forms gradually. A sac may exist for years and yet remain empty. When bowel or omentum enters it from some strain or effort, the parts were long prepared to receive the extruded mass. This extrusion may occur gradually or it may occur suddenly. If it occurs suddenly, the sufferer believes that his hernia was formed then and there, but, as a matter of fact, the extrusion of bowel or omentum and its entrance into the sac were but the last of a long series of antecedent and preparatory changes. Finally, a hernia appears, and often does so during effort. In rare cases traumatism may cause a hernia immediately, no sac existing before the accident. It does so in the inguinal region by stretching or tearing the internal ring, the inguinal canal at once enlarging. Such a condition is a true *traumatic hernia*, traumatism being the sole cause and not simply the exciting cause.

The old and erroneous idea was that a hernia was always formed by tearing of the peritoneum; hence the term *rupture*. This mode of formation is extremely unusual, but occasionally does occur. Coley saw such a case. An ordinary non-traumatic hernia, when the bowel suddenly and for the first time enters the sac, is the seat of some pain, but the pain is not disabling and the lump disappears on recumbency. In many cases the bowel or omentum gradually finds a way into the sac, and in such cases pain is usually trivial and may even be absent. In true traumatic hernia there are violent pain, collapse, vomiting, inability to walk and stand, and the mass does not return to the belly on recumbency, but must be reduced by taxis or operation. True traumatic herniæ may occur anywhere in the abdomen, but are most common in the inguinal region, where they are direct herniæ. (The relation born by accidents to the development of hernia is discussed by Paul Berger, in "Rev. de Chir.," April and May, 1906, and by Wm. B. Coley, in "Internat. Jour. of Surg.," Feb., 1908). All congenital herniæ are due to structural defects. Herniæ are divided clinically into *reducible*, *irreducible*, *incarcerated*, *inflamed*, and *strangulated*.

Reducible Hernia.—In this form of hernia the contents of the sac can be reduced into the abdominal cavity. At a known hernial opening the patient has a smooth enlargement (narrower above than below), which began to grow above and extended downward. A distinct neck can often be felt. In enterocele, straining, lifting, or standing enlarges the mass; the protrusion becomes smaller and may disappear on lying down; cough causes impulse or succussion, the protrusion is elastic, and may be tympanitic on percussion, and on reduction the mass suddenly disappears and there is a gurgling sound. In epiplocele the mass is often irregular and compressible, and feels boggy rather than elastic; muscular effort does not have much influence in enlarging it; impulse on coughing is slight; percussion gives a dull note, and reduction is accomplished gradually and produces no gurgling sound. In entero-epiplocele some parts of the mass are smooth, elastic, and perhaps tympanitic; others are dull on percussion, irregular, and flabby, but the diagnosis of this especial form from the other forms is often uncertain. The victims of reducible hernia complain of some pain on exertion, of dyspepsia, and often of constipation.

When a hernia is beginning to form there is often *premonotory uneasiness;* the patient complains of muscular pain in the lower abdomen, and this condition may exist for weeks or months before it is recognized that a hernia is present. An inguinal hernia can be recognized before it protrudes from the external ring. The tip of the finger is inserted in the ring and the patient is asked to cough. If a hernia has entered the canal, succussion will be detected on coughing. In a healthy man the external ring should admit the tip of the little finger, but not the end of the index-finger. If the end of the index-finger can be made to enter the ring that aperture is dilated, and even if there is no hernia in the canal, in future a hernia will probably descend. In a man, if the

surgeon desires to examine the ring, he inverts the skin of the scrotum over the finger and carries the finger to or in the ring. When the hernia first appears there may be pain, faintness, and some sick stomach, but often there is no pain or any discomfort.

Treatment of Reducible Hernia.—*Palliative Treatment.*—Prevent constipation and forbid sudden strains and violent exercise. If operation is refused or inadvisable, order a truss. The continued employment of a truss in young persons may bring about a cure. The day truss should be applied before rising in the morning and be removed after lying down at night, when a light truss should be substituted. A special truss is applied before bathing. In very fat people there is always trouble in adjusting a truss. A femoral hernia is more difficult to keep reduced than an inguinal hernia. In a hernia in which the gut is replaceable, but a portion of omentum is irreducible, it is difficult to maintain reduction of the gut with a truss, and an operation should be performed. In an oblique inguinal hernia the pad of the truss fits over the internal abdominal ring; in a direct inguinal hernia, over the external abdominal ring; in a femoral hernia, over the femoral ring at the level of Gimbernat's ligament. MacCormac's method of measuring for a truss is as follows: In either inguinal or femoral hernia start the tape from the *lower part* of the hernial opening, carry it up to the anterior superior iliac spine of the same side, then take it around the body, 1 inch below the crest of the ilium, to the other anterior superior iliac spine, and then to the upper part of the hernial opening.[1] A well-fitting truss will keep the hernia up even when the patient sits in a position to relax the abdominal walls and coughs and strains. A truss is always uncomfortable at first, but a person usually becomes accustomed to it. It should be kept scrupulously clean, and borated talc powder should be dusted upon the skin under the pad at least once a day. A truss which does not keep the hernia up or which causes pain does harm. Too strong a spring tends to enlarge the hernial orifice, and thus aggravates the case. Even after an apparent cure with a truss the instrument must be worn for a long time.

Radical treatment of reducible and of non-strangulated hernia seeks to obtain cure by plugging the mouth of the sac or by obliterating the canal of descent. Radical operations should be performed when a strangulated hernia is operated upon, in ordinary cases of reducible hernia, particularly if a truss is very painful or does not keep the bowel up, in most cases of irreducible hernia, and in any case of hernia in which there are occasional attacks of obstruction. It was formerly believed that a cure would fail if the subject was under three years of age, but Coley and others have proved that it is a very successful operation in childhood. It is rarely recommended under the age of four, because in two-thirds of the cases a truss will cure very young subjects. It is strongly advised in children after the age of four when a truss has failed, when there is irreducible omentum, or when there is a reducible hydrocele which prevents the truss from holding (Wm. B. Coley, in "Annals of Surgery," June, 1903). The radical operation is almost without danger in properly selected cases, and is one of the most successful of surgical procedures. We are justified in doing the operation upon an individual under fifty years of age and free from complications, purely to relieve him or her from the annoyance of wearing a truss. If, however, a patient is sixty years of age or over and a truss keeps the hernia up satisfactorily, the operation should not be performed unless it is demanded by some complication. Organic diseases of the heart, lungs, and kidneys are contra-indications. Enormous herniæ (Figs. 729 and 730) are unfavorable for operation. Restoration is difficult or impossible, the forcible handling produces much shock, and recurrence is to be expected.

[1] Treves's "Manual of Surgery," "Hernia."

Restoration is difficult or impossible because the abdominal cavity has contracted and holds with difficulty or cannot hold the huge hernia. As J. L. Petit said, the hernia has *forfeited the right of domicile* (Fig. 729). In an operation for an enormous hernia a great quantity of omentum will require removal, and it may be necessary to resect a considerable piece of intestine. If we decide to operate upon an enormous hernia, treat the patient some time before with the object of making him lose flesh. The absorption of mesenteric fat lessens intra-abdominal pressure. That operation may succeed in such cases is shown by Figs. 730 and 731. In any operation for the radical cure of inguinal hernia always remember that the *bladder* may be part of the hernia, and be on the lookout for it. Eggenberger's table of 6778 hernial operations shows 75 bladder herniæ (1 per cent.). As a rule, it is covered with cellular fat, which differs in color and consistence from omental fat and from other fat which may be found about a hernia. The presence of a quantity of extraperitoneal fat outside of the sac suggests the adjacency of the bladder and warns us not to tie off the sac very high up. It was the author's misfortune on two occasions to open a bladder in operating for inguinal hernia. In each case the bladder was sutured and both patients recovered. It has been estimated that the mortality after this accident, even when the bladder is sutured, is from 6 to 16 per cent. Among other possible accidents which may occur during hernia operations are: injury of an iliac vessel, of a femoral vessel, or of an epigastric vessel.

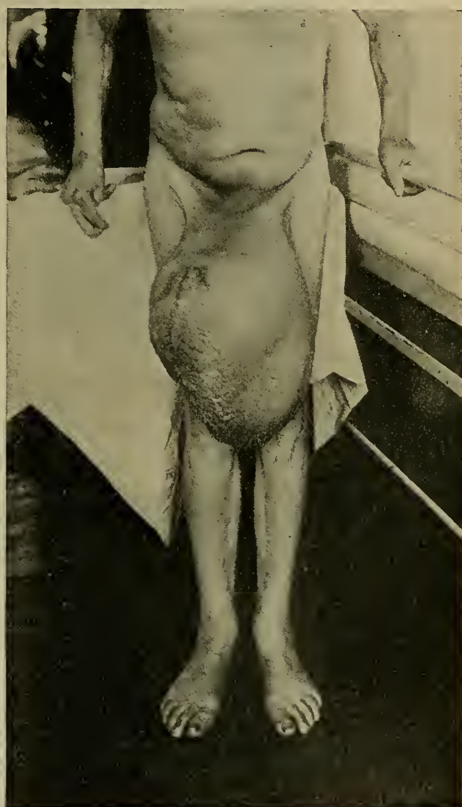

Fig. 729.—Hernia which has "forfeited the right of domicile."

The success of an operation for the radical cure of a hernia depends upon the attainment of primary union. Primary union is favored by thorough cleanliness; by wearing gloves while operating; by cutting the parts with a sharp knife instead of tearing them with a dissector; by removing some fat and any superfluous tissue fragments; by tying the stitches firmly, but not tightly (a tight stitch causes necrosis and creates a point of least resistance); by careful closure; by dressing with pressure; and by keeping the patient recumbent for from fifteen days to three weeks.

A truss is not to be used after operation. Ten years ago Wm. B. Coley ("Annals of Surgery," June, 1903) had operated upon 1075 cases of inguinal and femoral hernia. In his report he did not consider operations performed within the preceding six months, and so presented a study of 1003 cases. Of these, 937 cases were inguinal, 66 cases were femoral. In the 1003 cases, 647 were traced and were found well from one to eleven years after operation; 705

were well from six months to eleven years; 460 were well from two to eleven years. If the patient is well one year after operation, he will probably remain well. This is proved by Coley's study of relapses, an investigation which shows that

Fig. 730.—Oblique inguinal hernia of large size (duration, sixteen years).

65 per cent. of relapses occur within six months of operation and 80 per cent. within the first year. Only $13\frac{2}{3}$ per cent. occur from one to two years, and only

Fig. 731.—The case shown in Fig. 730 six months after operation.

$6\frac{2}{3}$ per cent. after two years. Coley had 2 deaths in 1075 cases (less than $\frac{1}{5}$ of 1 per cent.). After Bassini's operation there are about 1 per cent. of relapses. Coley reports that from Dec., 1891, to Jan., 1909, there were per-

formed by Drs. Bull, Walker, and himself, in the Hospital for Ruptured and Crippled, 2384 operations for the radical cure of hernia. Of these, 2218 were inguinal (only 445 in females). In the 1773 male cases the typical or modified Bassini operation was done with 12 relapses, or .68 per cent. ("Progressive Medicine," June, 1909).

Lannelongue's Method.—Lannelongue has for certain cases returned to the old injection plan, using a 10 per cent. solution of chlorid of zinc instead of white oak bark. The hernia is first reduced and is held up by an assistant, who closes the internal ring with a finger and also holds the cord aside. Several injections of 10 min. each are thrown in the region of the internal pillar, the region of the external pillar, and into the canal behind and outside of the cord. The surgeon must be careful that no zinc solution escapes into the subcutaneous tissue. The effect of the chlorid of zinc is to cause the formation of quantities of fibrous tissue. It is scarcely to be expected that a cure so produced will be permanent in an adult, though it may be in a child.

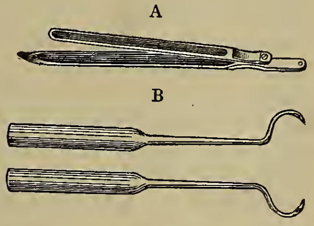

Fig. 732.—A, Hinged hernia director; B, hernia needles.

Macewen's Operation for Inguinal Hernia.—A hernia director (Fig. 732, A) and special hernia needles (Fig. 732, B) are required for this operation. The

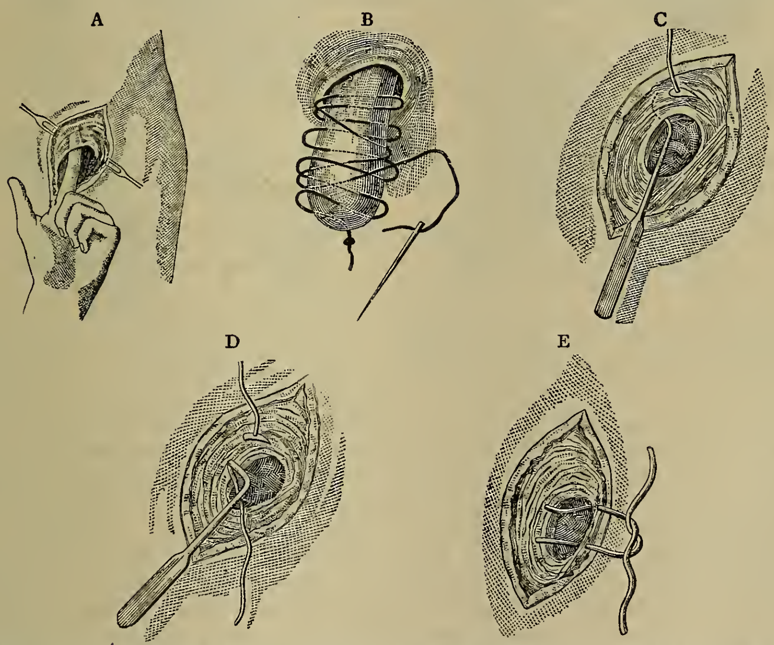

Fig. 733.—Macewen's operation for radical cure of inguinal hernia: A, Stripping of the sac: B, purse-string suture; C, fastening the purse-string suture; D, passing, and E, tying, the sutures for the internal ring.

patient lies recumbent, the thigh being abducted and partly flexed and resting on a pillow beneath the knee. The bowel is reduced, and an incision 3 inches long is made in the direction of the inguinal canal, the center of the incision corresponding to the external ring. The sac is freed from its attachments below and is lifted up. The surgeon introduces a finger into the inguinal

canal and separates the sac from the cord and from the walls of the canal, and then carries the finger through the internal ring and separates the peritoneum for 1 inch about the periphery of this aperture (Fig. 733, A). A chromicized catgut stitch is fastened to the lowest portion of the sac, and is passed through the sac several times, so that pulling on the stitch will purse the sac (Fig. 733, B). The free end of this stitch is carried through the internal ring into the belly, and is pushed out through the abdominal muscles 1 inch above the internal ring, the skin being pushed aside so as to escape perforation by the needle. The thread is tightened so as to fold up the sac and pull it into the belly. This plugs the ring. The thread is handed to an assistant to keep tight until the sutures are introduced into the ring, when the sac is permanently anchored by taking several stitches in the external oblique muscle. A strong catgut suture is passed with a Macewen needle through the conjoined tendon from below upward, the ends of this suture being carried through Poupart's ligament and the outer border of the internal ring from within outward. This suture is tightened and closes the internal ring. The external ring is sutured and the skin is stitched (Fig. 733, C, D, and E).

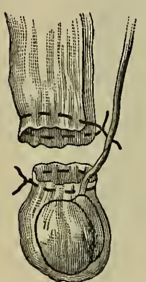

Fig. 734.—Macewen's operation for the radical cure of congenital hernia.

In congenital hernia the sac is divided in its middle, and the lower part is closed by stitches of chromicized catgut, forming a tunica vaginalis. The upper part of the sac is slit posteriorly to permit the escape of the cord, and is closed by stitches of chromicized catgut (Fig. 734). The operation is finished as in the acquired form. After Macewen's operation the patient should stay in bed for at least three weeks, and must not work for eight or nine weeks. Workmen after this operation should always wear for a time a pad and a spica bandage. Children require no pad. Never apply a truss, as strong pressure will produce atrophy of the curative scar.

Bassini's Operation for Oblique Inguinal Hernia.—(See E. Wyllys Andrews, in "Med. Record," Oct. 28, 1899, who describes from personal observation how Bassini does his operation. I have drawn upon his description in the following section.) Bassini's operation displaces the spermatic cord from the old canal and places it in a new canal, and this new canal is oblique. Curved and rounded needles are employed to insert the stitches. The suture material is kangaroo-tendon or chromicized catgut. Silk or silver wire is apt to make trouble—it may be long after the operation. The patient is placed supine with the thighs extended. An incision is made parallel to Poupart's ligament and extending from the external ring to a point external to the internal ring. The incision is about $1\frac{1}{2}$ inches above the ligament and is from 5 to 7 inches in length. By this incision the aponeurosis of the external oblique and the pillars of the external ring are exposed. All bleeding is arrested, the aponeurosis is incised in the direction of its fibers and from above downward, and the inguinal canal is opened. The aponeurosis of the external oblique is dissected up with a blunt instrument until Poupart's ligament is exposed. We speak of this ligament as the shelf. A mass containing the sac of the hernia, the cord, the cremaster muscle, and considerable fat is lifted up. Bassini employs blunt dissection. Coley advocates the use of the knife. Masses of fat and usually the cremaster muscle are removed. The sac is isolated first at its neck and the neck is stripped from the inner aspect of the internal ring for the distance of $\frac{4}{5}$ inch. The object of this stripping is to permit the removal of the sac at a high level. High removal obviates the leaving of a funnel-shaped depression of peri-

toneum. Such a depression would predispose to relapse. The sac is opened at the fundus, the interior is investigated, and if the contents are reducible, they are restored to the abdominal cavity and the neck of the sac is clamped high up. If adherent masses of omentum are found, the adhesions are separated, bleeding is arrested, and the omentum is restored to the abdomen unless it is in a hard and thick mass, when it is tied off and removed. Bassini ties off the neck of the sac above the clamp with a strong ligature of silkworm-gut. If the sac is large and thick, he also threads both ends of a ligature upon a needle, passes the strand through the stump, and ties around over the first loop. (See E. Wyllys Andrews, "Med. Record," Oct. 28, 1899.) Coley and many other operators prefer to tie off the sac with a catgut suture rather than with silkworm-gut or silk. It is my usual custom to employ fine black silk, catching it to prevent slipping by running a stitch through the wall of the neck of the sac. After ligating the neck of the sac the sac is cut across and removed. The cord is now lifted out of the way (Fig. 735, A), the inner surface of Poupart's ligament is exposed by retraction, and the deep sutures are passed (Fig. 735, A). Bassini uses silk which has been boiled in glycerin. Most

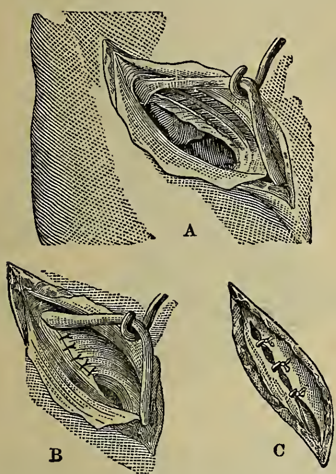

Fig. 735.—A–C, Bassini's operation for the cure of inguinal hernia (Esmarch and Kowalzig).

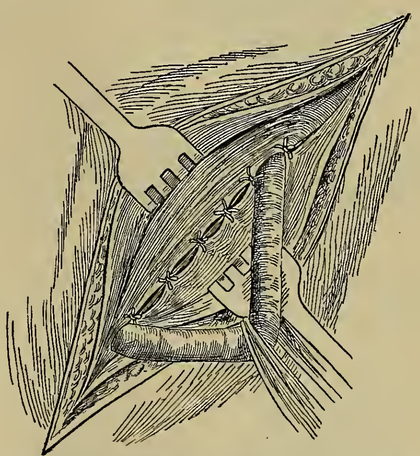

Fig. 736.—Bassini's operation (deep sutures), showing extra suture above the cord, as advised by Coley.

American operators use kangaroo-tendon or chromicized catgut. Bassini inserts first the sutures nearest to the pubes. The first suture—and sometimes also the second—includes part of the rectus sheath and rectus muscle. Each stitch includes the internal oblique and transversalis muscle in the upper edge and the shelf of Poupart's ligament below the lower margin, and from four to six stitches are passed behind the cord (Fig. 735, B). The last stitch narrows the internal ring so that it fits tightly around the cord (E. Wyllys Andrews, Ibid.). Coley's rule for passing this suture is to insert it so "that it just touches the lower border of the cord when the latter is brought vertically to the plane of the abdomen" ("Annals of Surgery," June, 1903). He always places a suture above the cord, and believes it tends to prevent relapse (Fig. 736). The sutures are tied from above downward. The cord is laid upon this new floor and the aponeurosis of the external oblique is sutured over it (Fig. 735, C). I close the aponeurosis by a continuous suture of chromic catgut and the skin with interrupted sutures of silkworm-gut or fine silk. Drainage is not used. The wound is covered with a roll of iodoform gauze and some pieces of sterile gauze, and compression is made by strips of adhesive plaster, and a piece

of adhesive plaster run from one thigh to the other acts as a shelf for the testicles to rest upon. The adhesive plaster is overlaid with dry gauze, and this is covered with absorbent cotton and the dressing is retained in place by a firm spica of the groin (*Coley's dressing*). The wound is dressed on the seventh or eighth day, and the patient is kept in bed for two weeks and is allowed to get about in two and one-half to three weeks, wearing a bandage until four weeks after operation.

In Bassini's operation some surgeons treat the sac as in Macewen's operation, carrying out the rest of the procedure as directed above. In a pure Bassini operation the funnel-shaped depression in the peritoneum at the point of emergence of the cord may remain and predispose to hernia, but the use of Macewen's plan for treating the sac obviates this.

Halsted's Old Operation (as described by J. C. Bloodgood, in "Johns Hopkins Hosp. Report," vol. vii).—The skin incision is not parallel to Poupart's ligament, but at an angle of 25 degrees to it (Fig. 737). Poupart's ligament is

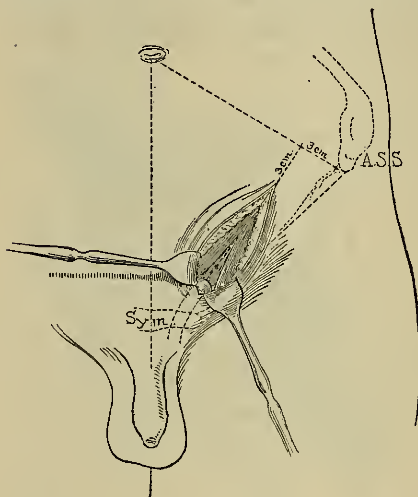

Fig. 737.—The skin incision, retractors in the lower angle of the wound dislocating the opening in the skin and subcutaneous fat downward, exposing the aponeurosis of the external oblique and external ring. The dotted line within the wound represents the direction of the division of aponeurosis of external oblique (Bloodgood).

Fig. 738.—The aponeurosis of external oblique has been divided and retracted, uncovering the internal oblique muscle and inguinal canal. The lines on the muscle represent the direction and extent of the division. The dotted line in the inguinal canal is the direction and extent of the division of the coverings of sac (Bloodgood).

well exposed to within 2 cm. of the pubic spine. The aponeurosis of the external oblique muscle is divided. Free the lower border of the internal oblique muscle and divide the edge of the muscle at a right angle to its fibers (Fig. 738), and as far as possible from the linea semilunaris. The coverings of the sac near the neck are picked up with mouse-toothed forceps and are divided. The division of the fasciæ is continued from the neck of the sac downward toward the pubes. The sac is then lifted from the inguinal canal and it brings with it "the larger bundle of veins and the vas deferens" (Fig. 739). The sac is separated from the veins and the vas with a knife or scissors, and the separation is carried to and beyond the neck of the sac. In "*certain cases* the larger bundle of veins is separated from the vas deferens, ligated, and excised" (Fig. 740). Whether the veins are excised or not, the sac is opened, its contents reduced, the opening into the peritoneal cavity closed with a continuous silk suture, and the excess of sac excised. During the entire operation the vas and its vessels "should be handled very little, and should not be torn from their bed

in the inguinal canal." Every point of bleeding should be ligated. At this stage the vas is gently picked up and a blunt-pointed hook is used to tear the mesocord. The freed vas is lifted into the upper angle of the divided internal oblique muscle, and is held there until the sutures are inserted. The deep

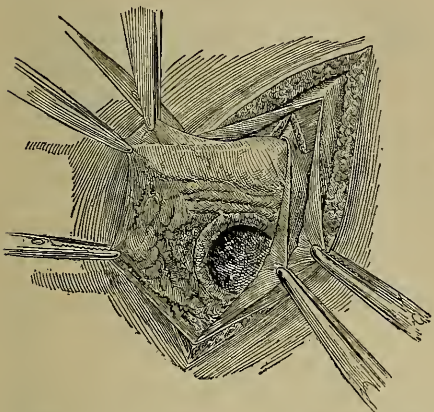

Fig. 739.—The internal oblique muscle and the coverings of the sac have been divided, the sac with the veins and vas deferens are drawn out of the wound preparatory to the excision of the sac and the ligation and excision of the veins (Bloodgood).

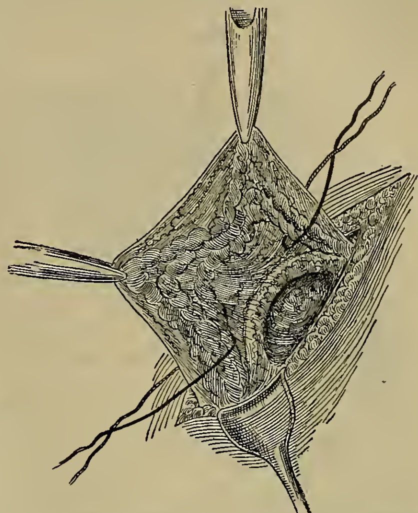

Fig. 740.—The method of excision of veins in operations for hernia and variocele. The vas deferens and its "immediate" vessels and the mesocord have not been disturbed (Bloodgood).

sutures of silver wire are next inserted. Usually five are needed. The upper one is passed first. These sutures are shown in Fig. 741. The cord emerges

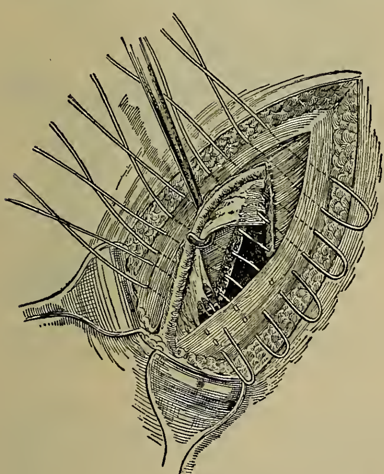

Fig. 741.—The insertion of the deep silver wire sutures, one above and four below the cord. The veins have been ligated and excised. The mesocord has been torn gently in its center only (Bloodgood).

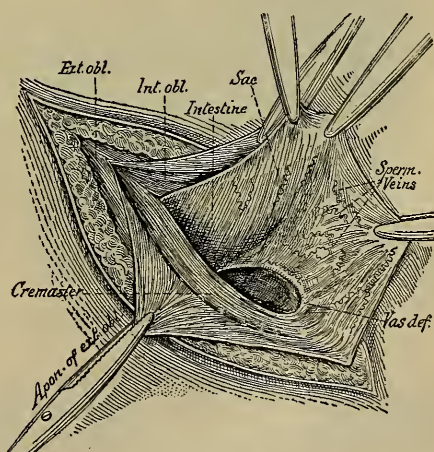

Fig. 742.—Exposure of the sac, the vas, and the spermatic veins (Halsted).

from the cut in the internal oblique muscle between the first and second sutures. Sutures No. 1 and No. 2 pierce the mesocord, but care is taken to see that they

do not injure the vas or its vessels. Each suture is drawn upon and twisted about six times. The cut and twisted ends are caught by forceps and turned in. The skin wound is closed with a subcuticular stitch of silver wire. It is covered with silver-foil and dry gauze, and often a plaster-of-Paris bandage and splints are used, "the splints extending from just above the knee to near the costal margins."

The Modified Halsted Operation.—The operation at present performed by Professor Halsted and his assistants has been evolved from the former operation so long associated with his name, and has been greatly modified by him and by Dr. Bloodgood. In this operation the skin and the aponeurosis of the external oblique are incised exactly as in performing Bassini's operation, and flaps of aponeurosis are raised. Next, the cremaster muscle and the cremaster fascia are incised in a line slightly above the center of the spermatic cord. The internal oblique muscle is then brought into distinct view at the side of the inguinal canal and the hernia is carefully inspected (Fig. 742). If the veins are found to be large they should be excised; but the surgeon does not lift the vas from its bed, and even avoids touching it, if he possibly can, for fear that thrombosis may occur in its veins. The veins are tied above, well up in the abdomen; and below, well above the testicle, and excised between the ligatures. The sac is then ligated or sutured with a purse-string suture. One end of the thread that ties or sutures the sac is carried, by means of a long, curved needle, in an outward direction under the internal oblique muscle, through which it is then pulled. The other end of the thread is also pulled through the muscle ½ inch from the first end, and these two ends are tied together. It will be observed that this treatment of the neck of the sac is somewhat similar to the method practised by Kocher.

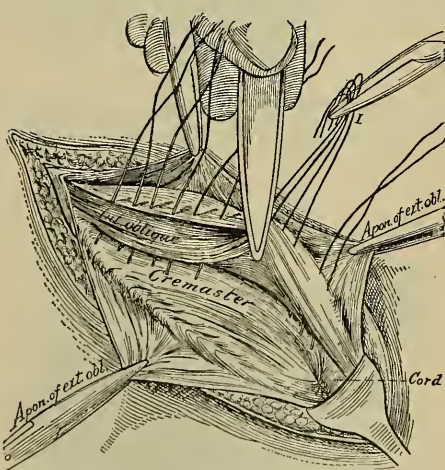

Fig. 743.—Suture of the cremaster to the internal oblique (Halsted).

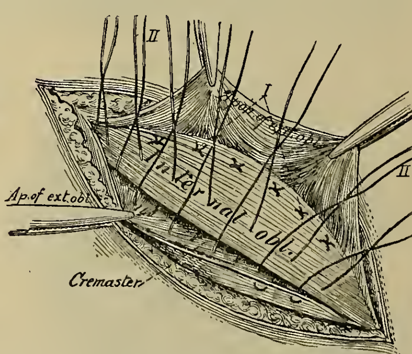

Fig. 744.—Suture of the lower edge of the internal oblique to Poupart's ligament (Halsted).

The next step is to carry the inferior flap, composed of cremaster muscle and fascia, under the internal oblique muscle, and suture it there (Fig. 743). We next suture the internal oblique muscle and the conjoined tendon to Poupart's ligament, the lower edge of the internal oblique being tucked under the edge of the ligament (Fig. 744). In order to accomplish this, it may be necessary to release the muscle by incising the anterior rectal sheath. The incision in the external oblique is now closed with sutures that overlap the margins (Figs. 745 and 746), and the skin wound is also closed.

Halsted's Operation Plus Bloodgood's Method of Transplanting the Rectus Muscle.—(See Jos. C. Bloodgood, in "Johns Hopkins Hosp. Reports," vol.

vii.) When the conjoined tendon is very thin or obliterated, the ordinary operation is not enough. Insufficiency of the conjoined tendon is known to exist when a finger does not meet any obstruction after passing through the

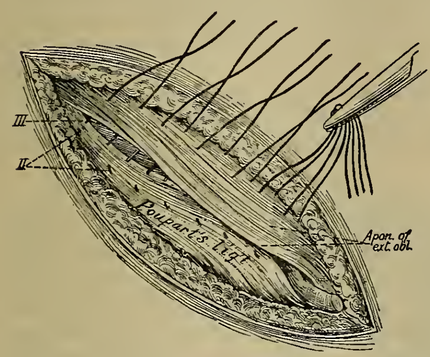

Fig. 745.—Suture of the aponeurosis of the external oblique (Halsted).

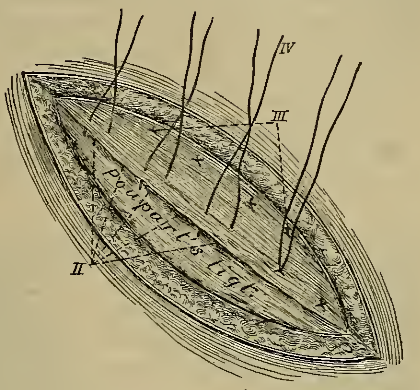

Fig. 746.—Suture of the margin of aponeurosis to Poupart's ligament (Halsted).

external abdominal ring, but can be introduced for some distance into the abdominal cavity (Bloodgood). To meet this condition of affairs, Bloodgood devised "a plastic operation on the rectus muscle, bringing this muscle down

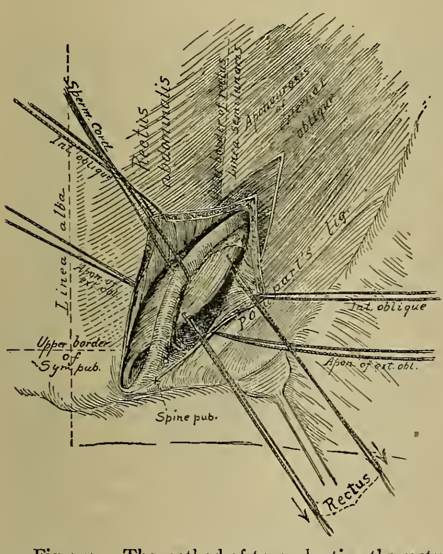

Fig. 747.—The method of transplanting the rectus muscle. The sac has been excised and the peritoneal cavity closed; internal oblique muscle has been divided, the rectus exposed and transplanted; at this stage the wound is ready for the deep sutures. This illustration shows how perfectly the transplanted rectus muscle lines the lower half of the wound (Bloodgood).

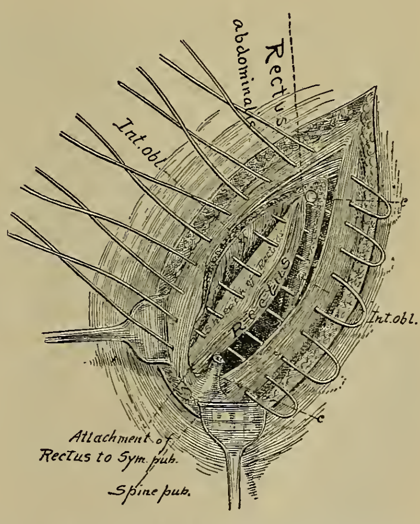

Fig. 748.—The transplanted rectus included by the deep sutures. In this illustration the cord has been excised in order to demonstrate the operation more clearly (Bloodgood).

and suturing it with the other available tissue to Poupart's ligament and to the aponeurosis of the external oblique from the arch of the pubis up to the position of the transplanted cord" (Bloodgood), in previously mentioned re-

port). The first steps of the operation are identical with those previously described, but before the insertion of the deep stitches the rectus sheath is exposed and divided in the direction of the muscle-fibers, from the pubic insertion upward for 5 cm. The muscle bulges from the cut and is caught with silk sutures (Fig. 747). Deep sutures are now introduced as in Halsted's operation, except that they include the rectus and its sheath (Fig. 748). The operation is completed as is Halsted's. I have performed this operation a number of times with entire satisfaction.

Kocher's Operation.—Kocher exposes the aponeurosis of the external oblique, makes a small incision through the aponeurosis above and external to the internal ring, and draws the sac through this incision and sutures it in place.

Fowler's operation is as follows: An incision is made parallel with Poupart's ligament from the spine of the pubis to the level of the internal ring, and a flap is turned up. The inguinal canal is opened and the sac and cord are isolated. The sac is opened, its contents reduced, it is cut off, and its edges grasped with forceps. The deep epigastric artery and vein are sought for, each is tied in two places and divided between the ligatures. The index-finger is introduced into the belly, and on this as a guide the floor of the canal is divided (transversalis fascia, subserous tissue, and peritoneum). The cord is placed in the peritoneal cavity. The edges of the opening are sutured so that broad serous surfaces are approximated, through-and-through sutures being passed from side to side. The cord is brought out at the inner end of the incision, the lower angle of the cut being at such a level that the cord curves upward and forward as it leaves the abdomen. The inguinal canal, the gap in the aponeurosis, and the skin wound are closed.[1]

Ferguson's Operation.—In studying a number of recurrences after operation A. H. Ferguson observed that a hernial protrusion is apt to return at the upper and outer portion of the scar, above the cord and near Poupart's ligament. When he operated upon relapsed cases, he discovered a slit of the aponeurosis of the external abdominal wall, through which the sac and some fat protruded. In order to determine the cause of the failure of these operations, he thought it proper to make a semilunar incision and raise a flap of skin, fascia, and aponeurosis of the external oblique. On doing this, he was surprised to find an angle between the lower border of the internal oblique muscle and the inner aspect of Poupart's ligament absolutely unprotected by the internal oblique or the transversalis muscle. In some cases this angle extended upward and outward to the anterior superior iliac spine. He, therefore, concluded positively that the cause of a rupture returning in this angle after an operation for radical cure is deficient origin of the internal oblique muscle and of the transversalis muscle at Poupart's ligament. He is now persuaded that in all cases of hernia there is a deficient origin of these muscles, and he has demonstrated the same thing in a series of dissections in the inguinal region. Ferguson describes his operation as follows ("Jour. Am. Med. Assoc.," July 1, 1899): He begins his incision over Poupart's ligament, $1\frac{1}{2}$ inches below the anterior superior iliac spine, carries it inward and downward in a semilunar curve, and terminates it over the conjoined tendon, near the pubic bone. The incision goes down to the aponeurosis of the external oblique, and the flap, with its fat and fascia, is turned downward and outward (Figs. 749 and 750). The next step is to incise the external abdominal ring to the intercolumnar fascia and separate the longitudinal fibers of the external oblique over the inguinal canal to beyond the internal ring, at a point nearly opposite the anterior superior spine of the ilium. Any transverse fibers that may be encountered are severed. The separated aponeurosis of the external oblique muscle is then retracted. One has then

[1] "Annals of Surgery," Nov., 1897.

brought into view the contents of the inguinal canal, the hernial sac and its adhesions, the spermatic cord, the ilio-inguinal nerve, the internal abdominal ring, the subserous fat, the cremaster muscle, the conjoined tendon, the internal oblique and its deficient origin at Poupart's ligament, the transversalis fascia, and the internal surface of Poupart's ligament. The sac is now dissected from

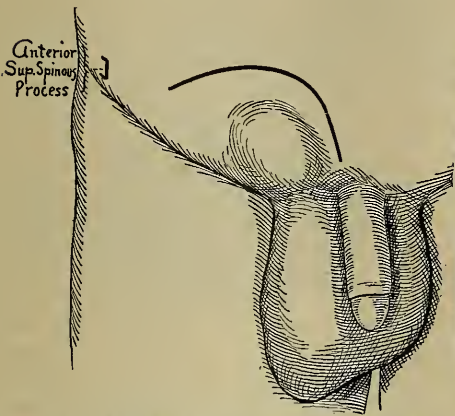

Fig. 749.—Ferguson's operation: The semilunar skin incision ("Jour. Am. Med. Assoc.").

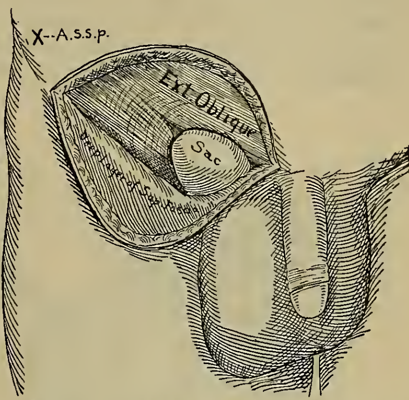

Fig. 750.—Ferguson's operation: Flap turned back exposing the aponeurosis and the sac of the hernia ("Jour. Am. Med. Assoc.").

the cord and the internal ring. It is opened and its contents are inspected and properly dealt with. It is tied high up and cut off, and the stump is dropped into the abdomen (Fig. 751). If the sac is congenital it is divided into two parts: the distal portion is used to make a tunic for the testicle and the proximal

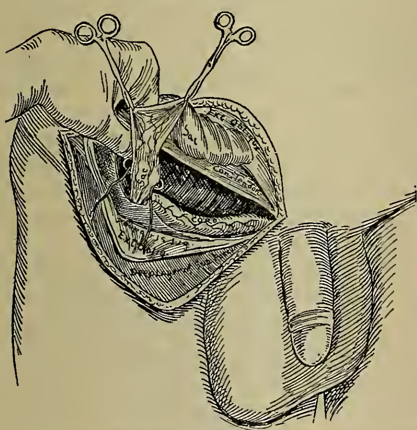

Fig. 751.—Ferguson's operation: Dealing with the sac and its contents ("Jour. Am. Med. Assoc.").

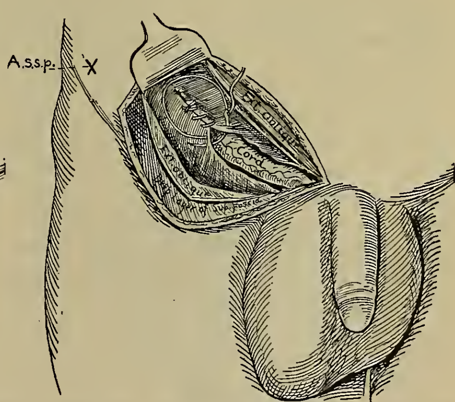

Fig. 752.—Ferguson's operation: Suture of the slack in the transversalis fascia ("Jour. Am. Med. Assoc.").

portion is treated as above directed. The cord is not disturbed, and it is beyond doubt that Ferguson is right in saying that the testicle frequently comes to harm after operations that disturb the cord. The veins in the cord should not be touched unless a varicocele also exists. Any excessive quantity of subserous adipose tissue should be removed. The next step in the operation is

to restore the structures to their normal position; and one should remember that in the transversalis fascia is the internal ring. In hernia the internal ring is large and the transversalis fascia bulges outward; one must, therefore, take up the slack in this fascia and make a well-fitting ring for the cord by means of a catgut suture, either interrupted or continuous (Fig. 752). After this has been accomplished the internal oblique and transversalis muscle are sutured to the internal aspect of Poupart's ligament, after the lower borders of the muscles have been freshened and Poupart's ligament has been scarified. The sutures must be carried two-thirds of the way down Poupart's ligament, which is about the normal origin of this muscle in the female (Fig. 753). The next step is to suture the edges of the divided aponeurosis of the external oblique; this restores the external abdominal ring. The skin-flap is then carefully sutured.

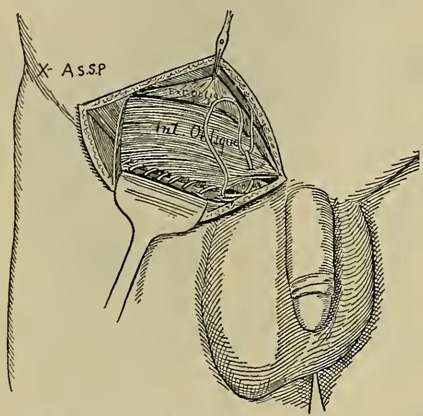

Fig. 753.—Ferguson's operation: Suture of the internal oblique and of the transversalis muscle to the internal aspect of Poupart's ligament ("Jour. Am. Med. Assoc.").

Radical Cure of Direct Inguinal Hernia.—If the hernia goes through the conjoined tendon or pushes that structure before it, the operation should consist in transplanting the rectus muscle as practised by Bloodgood (see page 1145) and suturing the arched fibers of the internal oblique and conjoined tendon to Poupart's ligament and beneath the cord.

If the hernia passes around the outer edge of the conjoined tendon an overlapping operation, like the Mayo operation for umbilical hernia, should be performed (G. G. Davis, in "Annals of Surgery," Jan., 1906).

Radical Cure of Umbilical Hernia.—The results of operations for umbilical herniæ have not been satisfactory. Recurrences are frequent. This is probably due to the fact that most of the subjects are fat, and that the muscles are thin and flabby. The usual operation may be thus described: Make a longitudinally elliptical incision through the skin around the mass. Endeavor to separate the sac from the superficial tissue. If this cannot be done, open the sac and separate it from the contents. Even if the sac can be stripped from the skin, always open it and separate the contents. Return any bowel which may be present, and do not forget that there may be a small portion of bowel completely encased in omentum. Tie into segments and cut off the superfluous omentum and return the stump into the belly. Excise the umbilicus (*omphalectomy*). Suture the peritoneum with a continuous catgut suture. Close the musculofascial wall with two layers of interrupted sutures of kangaroo-tendon or chromic catgut, or one layer of silver wire mattress sutures. Close the skin by interrupted sutures of silkworm-gut or a subcuticular stitch.

Mayo's Operation.—This is a vast improvement on the older operation. It gives a firm cicatrix free from disastrous traction. Mayo believes that the defect in the old operation is that the recti muscles are naturally separated at the level of the umbilicus, and in bringing the recti together we have virtually performed muscle transplantation, and these thin muscles are of no great value in preventing relapse, and in a large hernia it is not even possible to cover the gap by muscle. Mayo now operates as follows: Transverse elliptical incisions are made around the umbilicus and hernia and the base of the protrusion is exposed (Fig. 754). The surface of the aponeurosis is cleared for $1\frac{1}{2}$ inches around the neck of the sac. The fibrous and peritoneal coverings of the hernia

are divided by a circular incision around the neck of the sac. Intestine is freed from adhesions and placed within the abdomen. Omentum is ligated and removed with the sac. The margins of the ring are grasped and overlapped in order to indicate in which way it can be most easily done; thus is the direction of the closure indicated. An incision is made through the fibrous and peritoneal coverings of the ring 1 inch or more transversely on each side, and

Fig. 754.—Mayo's operation for the radical cure of umbilical hernia: Exposure of hernia and lateral incision.

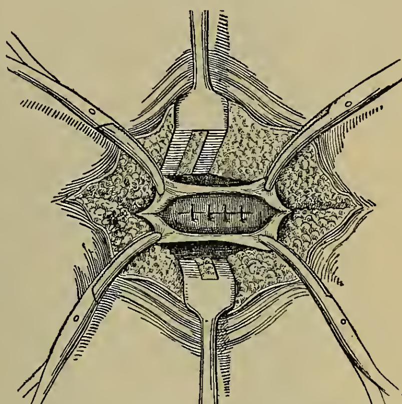

Fig. 755.—Mayo's operation for the radical cure of umbilical hernia: Peritoneum sutured.

the peritoneum is stripped from the under surface of the upper flap. Several mattress sutures of silver wire are introduced 1 inch above the edge of the upper flap and are carried through the margin of the lower flap; sufficient traction is made to permit of the closing of the peritoneum with a continuous catgut

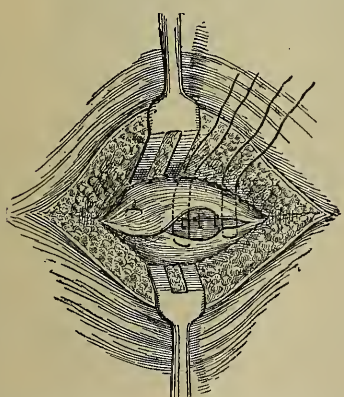

Fig. 756.—Mayo's operation for the radical cure of umbilical hernia: Aponeurosis sutured.

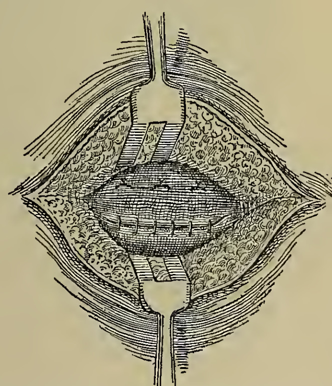

Fig. 757.—Mayo's operation for the radical cure of umbilical hernia: Aponeurosis sutured second time with gut sutures.

suture (Fig. 755). When this has been accomplished, the silver wire sutures are drawn so as to slide the lower flap into the pocket between the peritoneum and the under surface of the upper flap (Fig. 756). The free margin of the

upper flap is fixed by catgut sutures to the aponeurosis (Fig. 757), and the superficial incision is closed as usual. Wm. J. Mayo ("Jour. Am. Med. Assoc.," June 1, 1907) reported upon 88 operations for umbilical hernia by this method between 1894 and 1905; 75 were traced; 1 had a partial relapse; 1 was supposed to have a relapse, but operation disclosed a second opening above and outside of the closed umbilical opening.

Radical Cure of Femoral Hernia.—Cheyne ligates the neck of the sac, stitches the stump to the abdominal wall, dissects out a flap from the pectineus muscle, stitches this flap to Poupart's ligament and to the abdominal wall, and thus fills up the crural canal. Bassini makes an incision parallel to Poupart's ligament, ties the neck of the sac, cuts off the sac below the ligature, and returns the stump into the belly. He attaches by deep sutures Poupart's ligament to the pectineal aponeurosis as high up as the pectineal eminence, the cord or round ligament being drawn out of the way. Superficial sutures are passed between the pubic portion and the iliac portion of the fascia lata.

Fig. 758.—Fabricius's operation for the radical cure of femoral hernia: Neck of sac shown. Sac cut away. Dotted line shows line of separation of Poupart's ligament and fascia lata (Fowler).

The *operation of Fabricius* is very satisfactory. It is performed as follows: An incision is begun over the pubic spine and is carried outward for 5 inches parallel with Poupart's ligament. The sac is exposed, isolated, and opened, its contents are reduced, its neck is ligated, the sac is cut off, and the stump is dropped back (Fig. 758). An incision is now made below Poupart's ligament so as to separate this structure and the fascia lata, and the flap of fascia is turned down (Fig. 759). The crural sheath and the vessels are retracted outward. The surgeon is careful not to injure the obturator artery and vein. The origin of the pectineus muscle is sutured to Poupart's ligament. The lower stitches include the periosteum of the horizontal ramus of the pubes as well as the beginning of the muscle (Fig. 760). Care must be taken in passing certain of them to avoid injuring the deep epigastric vessels. When these stitches are tied, the femoral canal is obliterated. The flap of fascia lata is sutured to the aponeurosis of the external oblique, and the skin is sutured.

Operative Treatment of Adherent (Sliding) Hernia of the Ascending and Descending Colon.—My personal experience consists of 8 cases of right and 2

cases of left inguinal hernia. The sac is deficient posteriorly and externally (see page 1161). In order to restore the bowel into the abdomen many opera-

tors have sought to force up the adherent intestine to the external ring, and others have stripped the gut from the subperitoneal tissues in order to per-

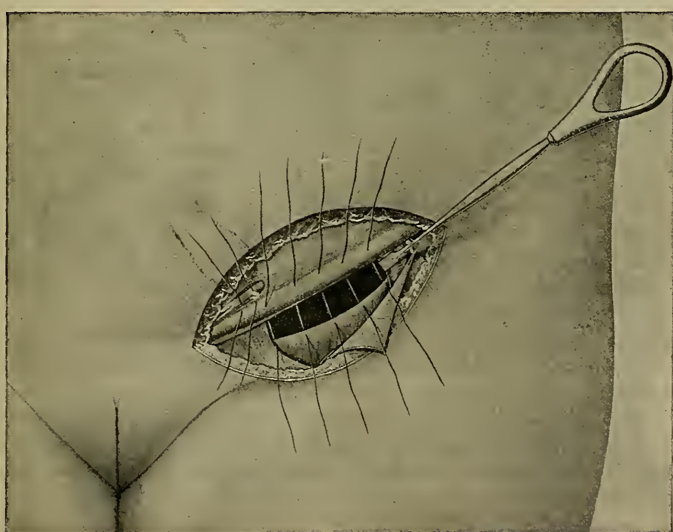

Fig. 760.—Fabricius's operation for femoral hernia: Crural sheath and vessels retracted and kangaroo-tendon sutures applied to Poupart's ligament and origin of pectineus, ready for tying. Two sutures are placed in position to approximate the pillars of the external ring (Fowler).

mit of reduction. The first plan should never be followed. If it should be employed, sutures will fail to hold the bowel up. The second plan is risky and may be followed by gangrene of the bowel. In my cases I followed

Weir's plan ("Med. Record," Feb. 24, 1900), and, after dissecting up the peritoneum on each side to a little above the internal ring, freed the bowel from its bed and covered the new surface with the peritoneal flaps (Fig. 761). The bowel was then restored and a radical cure was made.

Irreducible Hernia.—The swelling in irreducible rupture presents the usual evidences of hernia, imparts an impulse on coughing, but cannot be replaced in the abdomen. Sometimes a portion is reducible and a portion is irreducible. A hernia may become irreducible because of the size of the mass, because of adhesions, or because of excessive growth of omental fat. An irreducible hernia is liable to be bruised and to cause much distress and pain, and is always a menace to life because of the danger of obstruction and strangulation. It was formerly the custom to support a small irreducible hernia by a hollow, padded truss, but now operation should be advised. A large hernia of this variety, if operation is refused, must be carried in a bag truss. The patient must not take very active exercise, must keep the bowels regular, and must live upon a plain diet. Most cases of irreducible hernia should be treated by operation.

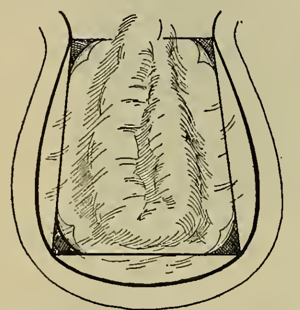

Fig. 761.—Outline of peritoneal lining of sac utilized as a flap to cover posterior surface after it has been freed by dissection (Weir).

Incarcerated or Obstructed Hernia.—Obstruction takes place by the damming up of feces or of undigested food, the fecal current being arrested, but the blood-current in the wall of the bowel not being cut off. Incarceration is commonest in irreducible hernia, especially umbilical hernia, and during the existence of constipation. The hernia enlarges and becomes tender, painful, and dull on percussion; pressure may diminish it somewhat in size. It remains irreducible, but still presents impulse on coughing. The abdomen is somewhat distended and painful; there are nausea, constipation, and not unusually slight vomiting. Constitutional disturbance is trivial and constipation is not absolute, gas at least usually passing. Vomiting is not fecal.

The *treatment* is rest in bed in a position to relax the belly, an ice-bag over the hernia for a very few hours, and a little opium for pain. Do not give a particle of food for twenty-four hours; when the active symptoms subside give an enema, and, after this acts, a dose of castor oil. Do not employ taxis, as bruising the bowel may produce strangulation. If improvement does not rapidly occur, operate. Prompt operation saves the patient from the danger of strangulation and cures the hernia.

Inflamed Hernia.—Inflammation of a hernia is local peritonitis due to injury of an irreducible hernia. The mass becomes tender and painful, and perhaps heat is noted. In enterocele much fluid forms; in epiplocele the mass becomes hard. The hernia cannot be reduced; there is constipation, often vomiting, usually elevated temperature, but the mass still shows impulse on coughing. Vomiting is not fecal. Some gas is usually passed through the bowels. Constitutional symptoms are slight.

The *treatment* usually recommended is rest in bed with abdominal relaxation, an ice-bag to the tumor for a few hours, a small amount of opium by the mouth if pain is severe, an enema, and, after this acts, a saline. In an inflamed hernia there is great danger of strangulation, and operation should be performed in preference to relying upon the conservative plan.

Strangulated hernia is a condition in which, if the hernia contains bowel, not only is the fecal circulation arrested and gas prevented from passing, but the circulation of blood in the bowel wall is also arrested. The bowel is

irreducible and obstructed, and the blood ceases to circulate. If the hernia contains omentum, the omental vessels are tightly constricted. In both bowel and omentum gangrene soon occurs, but sooner in bowel than in omentum. Strangulation is commonest in old inguinal ruptures in active, middle-aged men, and is more frequent in enteroceles than in epiploceles. It is most common when the hernial orifice is small and is seldom seen in large ruptures.[1] Strangulation is rare in childhood. Strangulation is much more dangerous if bowel is present in the sac than if only omentum is present. If in a subject of hernia the abdominal pressure is suddenly increased, as by a violent cough or a muscular effort, the hernial orifice is dilated for a moment, more intestine or omentum may enter the sac, and if it does, it may be caught and constricted by the now constricted hernial orifice and strangulation begins. Strangulation so caused is called *elastic strangulation.* A sudden increase of intra-abdominal pressure may force a quantity of fecal matter into the herniated intestine. The sudden entry of a quantity of fluid and gas into the herniated coil causes *fecal strangulation*, the mechanism of which is obscure. By *retrograde strangulation* we mean a condition in which the end of a loop of bowel or a piece of omentum in a hernia re-enters the abdomen and then becomes strangulated, the balance of the hernia not being strangulated. Strangulation may be due to active peristalsis or to congestion, and it may arise from inflammation or from incarceration. The constriction may be at the neck of the sac, in the outside tissues, or even in the sac itself. In an hour-glass hernia the constriction may be in the body of the sac. In inguinal hernia a tight external ring is a common cause of strangulation and is the commonest cause in children. As Coley shows, the neck of the sac is very seldom the cause in children. Adhesions within the sac may cause strangulation. Spasmodic contraction of the tissues about the neck of the sack is an exploded hypothesis. The obstructed veins dilate and the blood in them ceases to move, the bowel becomes deep bluish and finally black, effusions of blood occur beneath the peritoneum, and the intestinal wall becomes edematous. Fluid transudes into the sac, and the fluid, at first clear, assumes a bloody hue, and finally becomes dry and foul. The peritoneum ceases to glisten, becomes dry and rough, and coated here and there with lymph. Strangulated omentum undergoes edema and hemorrhagic infarction and thrombosis occurs. When strangulation once begins the hernia swells, a furrow forms on the bowel at the seat of constriction, the bowel and omentum below the constriction become deeply congested and edematous, and, finally, the hernia passes into a state of moist gangrene (Fig. 763). The gangrene may be in spots or the entire mass may be gangrenous. The mucous membrane may be gangrenous when the serous coat looks fairly

Fig. 762.—Strangulated umbilical hernia containing nearly all the intestines and part of the stomach. Strangulation under bands within the sac.

[1] Strangulation developed in the large herniæ shown in Figs. 730 and 762.

sound. When gangrene is once established, the bowel is in danger of rupturing. At the point of constriction there may be a line of ulceration or of gangrene even when the balance of the gut looks fairly safe. A strangulated femoral hernia becomes gangrenous more rapidly than a strangulated inguinal hernia.

Symptoms.—This condition is sometimes preceded by diarrhea and uneasiness or pain about the hernial orifice. When strangulation begins the victim is seized with pain in and about the hernia and with violent colicky pain about the umbilicus, and the paroxysms of colic become more and more frequent, until finally the pain may become continuous. The hernia is found to be irreducible; larger than usual, tender, painful, dull on percussion, without impulse on coughing, and the skin above it may be reddened. Eructations of gas are frequent, and generally uncontrollable vomiting and prostration come on. Vomiting, as a rule, is an early symptom, and one which increases in severity. Occasionally it only follows the swallowing of liquids. Not unusually there is retching rather than vomiting. In rare cases vomiting does not begin for twenty-four to forty-eight hours. Vomiting is earlier and more violent when bowel is present in the sac than when the hernia is purely omental. During the course of a strangulation vomiting may cease for a day or more, and it not unusually ceases toward the end, when prostration is profound. The early vomiting is due to reflex causes; the later vomiting is due to waves of peristalsis which produce regurgitation (Macready's "Treatise on Ruptures"). The vomiting is first of the alimentary contents of the stomach, next of mucus and bilious matter, and finally of the contents of the small bowel (*fecal* or *stercoraceous vomiting*). Stercoraceous vomiting rarely arises until strangulation has lasted forty-eight hours, and may not appear until much later. "It is seldom met with in inguinal, more often in femoral, and more often still in obturator, hernia" (Macready, Ibid.). Prostration is a marked symptom of a strangulated hernia, and it increases hour by hour and goes on to collapse. Early in the case there may be some elevation of temperature, but later it becomes normal or subnormal. The pulse is small, irregular, rapid, and very weak; the extremities cold; the face becomes Hippocratic. Constipation is absolute, no gas even being passed, though in the very beginning there may be some diarrheal passages from below the constriction. The urine is scanty and high colored, and contains only a small amount of the chlorids; the tongue becomes dry and brown; the thirst is torturing, and the patient often has an imperative desire to go to stool. Pains in the abdomen and in the hernia become more and more violent, and collapse rapidly increases. When gangrene begins the symptoms apparently lessen in violence: there is a *delusive calm.* Vomiting usually ceases, though regurgitation may take its place; hiccup begins; the pain abates or disappears; the pulse becomes very frequent, feeble, and intermittent; collapse deepens, and delirium is usual. It is a safe clinical rule that in strangulated hernia sudden cessation of pain without the relief of constriction, the disappearance of the lump, or the use of opiates means that gangrene has begun. In some cases of strangulation there are muscular

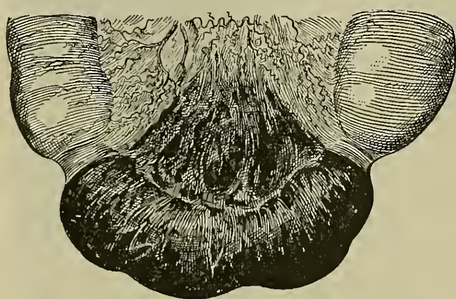

Fig. 763.—A strangulated coil of intestine after the strangulation existed for a considerable period of time. The color has become almost black and the peritoneal surface is dull and covered with flakes of fibrin. The constriction rings are deeply sunken, their walls markedly thinned, relaxed, and dirty gray in color. Both constriction rings are gangrenous and hemorrhages are observed in the mesentery (Sultan).

cramps in the legs (Berger). In children convulsions are not unusual. In a pure omental hernia strangulation produces similar but less decided symptoms. It may be that only a portion of the circumference of the bowel is caught and constricted in a hernial orifice (see Fig. 770, A). Such a condition is encountered occasionally in the femoral ring, and is called *partial enterocele* or *Richter's hernia.* The name *Littré's hernia* is often wrongly given to this condition. What Littré described was a hernia of Meckel's diverticulum (see Fig. 770, B). In a strangulated Richter's hernia constipation is rarely absolute and often no protrusion is discovered.

Treatment.—In treating strangulated hernia place the patient upon his back, bend the knees over a pillow, and rigidly interdict the administration of food. An attempt may usually be made to effect reduction by gentle manipulation or *taxis.* In applying taxis to a femoral or inguinal hernia, flex and adduct the thigh of the affected side. In applying taxis to an umbilical hernia both thighs should be flexed upon the abdomen. Always lower the shoulders and head and raise the pelvis, and accomplish this by lifting the foot of the bed and placing pillows under the pelvis. In some cases raise the entire body and lower the head. Grasp the neck of the sac with the fingers and thumb of one hand, and employ the other hand to squeeze the hernia and urge it toward the belly. In direct inguinal hernia the pressure should be backward and a little upward; in umbilical hernia it should be backward; in oblique inguinal hernia it should be upward, outward, and backward; in femoral hernia it should be downward until the hernia enters the saphenous opening, and then "backward toward the pubic spine" (MacCormac, in Treves's "Manual of Surgery"). If the bowel should be reduced, it will pass from the hand with a sudden slip and enter the belly with an audible gurgle; omentum, when reduced, slowly glides back without gurgling. Taxis is never to be continued long, and it is not even to be attempted in cases of great acuteness, in cases in which strangulation has lasted for several days, in cases known to have been previously irreducible, in cases associated with stercoraceous vomiting, or in inflamed or gangrenous herniæ.

If taxis fails, obtain the patient's permission to operate. Anesthetize; in some cases try taxis again upon the unconscious patient and while ether is being dropped upon the hernia to cause cold; if reduction fails, at once perform herniotomy. Taxis possesses certain dangers: It may rupture the bowel; it may rupture the neck of the sac and force the bowel through the rent into the tissues of the abdominal wall; it may strip the peritoneum from around the hernial orifice and force the bowel between the detached peritoneum and the abdominal wall; it may reduce a hernia into the belly when the bowel is still strangulated by adhesions; it may reduce the hernia *en masse* or *en bloc.* By the term "reduction *en masse*" we mean that the sac has been separated and dislocated and with the constricted bowel within it has been forced through the internal ring. By "reduction *en bissac*" is meant the forcing of a congenital hernia into a congenital pouch or diverticulum. Reduction *en masse* is a rare accident. Corner and Howitt ("Annals of Surgery," vol. xlvii) collected 137 cases of reduction *en masse* of strangulated hernia. Of these, 110 were males, 113 were inguinal, 22 femoral, and 2 obturator herniæ. No ventral or umbilical cases are recorded. The accident is a very dangerous one. According to Corner and Howitt (Ibid.), the mortality after inguinal reductions *en masse* is 48 per cent., and after femoral reductions, 72 per cent. Strange to say, reduction *en masse* can occur spontaneously. The subject most liable to reduction *en masse* is an elderly person with an old hernia. In acute cases the small bowel is the viscus which was reduced. In subacute and chronic reductions *en masse* the omentum, large bowel, or bladder was reduced (Corner and Howitt, Ibid.). Subacute and chronic cases may

happen in non-strangulated hernia. In any of the above accidents obstruction may persist after apparent reduction by taxis. Persisting obstruction means strangulation or peritonitis and calls for instant laparotomy—in most instances through the hernial aperture. If taxis is successful, put the patient to bed, apply a pad and bandage, allow no food until vomiting ceases, merely permit him to take a little hot water during the first twenty-four hours, and keep him on a liquid diet for several days. At the end of the first week give solid food. Do not disturb the bowels for a few days, but if they have not acted when four or five days have elapsed since the operation, give a saline cathartic followed in a few hours by a purgative enema. There is usually a spontaneous movement within twenty-four hours after reduction by taxis.

Herniotomy.—If there has been stercoraceous vomiting the stomach must be washed out before giving the anesthetic, and during the administration of the anesthetic the head should be turned upon its side. In most cases a general anesthetic can be given, but in desperate cases it is not justifiable to give ether or chloroform, and a local anesthetic must be used (infiltration anesthesia). Wrap the patient up in blankets. In most cases try gentle taxis for a brief time after the patient has been anesthetized and while ether is being dropped upon the hernia to cause cold. Never try taxis if stercoraceous vomiting has occurred. If taxis fails, at once sterilize the parts and operate. Always lay out a hernia knife (Fig. 764), a director (see Fig. 732, A), and Murphy buttons. During the *operation* the patient lies

Fig. 764.—Cooper's curved herniotome.

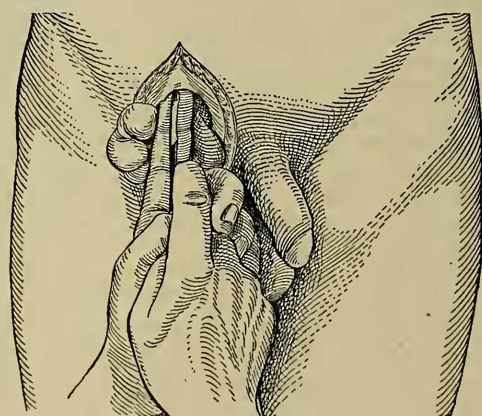

Fig. 765.—The division of the constriction from within outward (Sultan).

upon his back with the shoulders raised, the surgeon standing to the patient's right side. In *oblique inguinal hernia* it has been the custom since the days of Scultetus to raise a fold of skin at a right angle to the axis of the external ring and transfix it, the wound which results being extended until it becomes 3 inches in length. This incision possesses no special merit. It is better to cut from without inward, and to make the same incision as for the performance of a radical cure in a non-strangulated case. The superficial tissues are divided, the aponeurosis is opened as in Bassini's operation, and the sac is reached. In most cases the constriction is relieved as soon as the external ring is nicked, and in many cases fibrous adhesions will be found in that region, gluing the sac to the ring. The sac must be identified; and it is known by the fat which usually covers it, by the fluid within the sac, by the arborescent

arrangement of its vessels, and by the fact that it can be pinched up between the finger and thumb and the layers rolled over each other. Should the sac be opened? It may not be actually necessary in every recent case, but if there is any doubt as to the condition of the bowel or if a radical cure is to be attempted, open the sac and be certain as to the condition of its contents. As there is always some doubt as to the condition of the contents, and as a radical cure is to be made, make it a rule to always open the sac. The sac is opened and the contents examined for fecal odor (which is not unusual) and for gangrenous smell; the thickness of the bowel is estimated and the color and luster are determined. If a constriction exists at the neck, it is nicked with a hernia knife. If the hernia is oblique inguinal and is caught at the internal ring, nick the constriction upward and outward or directly upward, as shown in Fig. 765. In direct inguinal hernia and in an oblique inguinal hernia caught at the external ring the cut is made upward and inward. Always pull the bowel down and examine the seat of constriction to see what damage has been inflicted at that point. If the serous coat glistens; if the proper color comes back to the bowel wall after irrigation with very hot water; and if there are no spots of gangrene, restore the bowel to the abdomen and do a radical cure. If the bowel is in a doubtful condition, fasten it to the incision, apply a dressing, and watch the development of events. If the bowel is gangrenous, our action depends upon the condition of the patient. If the patient is in good condition, resect the gangrenous portion and perform end-to-end approximation. If the patient's condition is bad, draw the gangrenous portion well out, anchor it to prevent leakage and retraction, make an artificial anus, and at a later period perform anastomosis. An artificial anus can be made by the method of Bodine (see page 1122). Unfortunately in these cases the artificial anus must usually be made in the small intestine. In many cases in which there is some uncertainty as to the need for an artificial anus prepare the bowel for the opening, but do not open at once, because the bowel may recover in a day or two, when it can be restored to the belly, or it may slough and form an artificial anus. In such doubtful cases fasten the bowel to the belly wall with sutures, dust it with iodoform, dress it with hot antiseptic fomentations, and await future developments. Gangrenous omentum requires ligation and resection. If the bowel is fit to reduce, push it just inside the ring, irrigate the parts, suture, and perform a radical cure. In *femoral hernia* we can make the incision 1 inch internal to and parallel with the femoral vessels and crossing the tumor and ligament (Barker); but it is better to make the incision of Fabricius for radical cure. Divide the constriction by cutting upward and a little inward. If the gut is found gangrenous or in a doubtful condition, follow Blake's advice ("Surg., Gynec., and Obstet.," May, 1906), make an incision at the edge of the rectus, draw the affected portion of gut into the abdomen and out of the incision, and either resect, fix it under or out of the incision, or wait for return of circulation, as may be indicated in the case. To draw the gut out of the femoral ring makes so much traction that return of circulation may be prevented, and any intestinal operation is difficult in this region without splitting Poupart's ligament. In *umbilical hernia* make a slightly curved incision a little to one side of the middle of the tumor, open the sac, separate adhesions, and divide the constriction by cutting upward or downward, and sometimes also laterally, or, better, operate as for radical cure (see page 1148).

After an operation for strangulated hernia put the patient to bed; bend the knees over a pillow; give no food by the mouth for thirty-six hours (MacCormac), only allowing hot water, and every sixth hour give an enema of salt solution containing brandy. Abdominal pain and tenderness call for the administration of saline cathartics and enemata containing turpentine or oil of rue. The enema rutæ is a favorite preparation in St. George's Hospital,

London. It is made as follows: Take 16 oz. of an infusion of camomile, warm it, and pour it upon 3 dr. of confection of senna (Sheild). If there is no abdominal pain and no tenderness the bowels need not be disturbed for a few days; but if at the end of four or five days they have not acted, give a saline cathartic and a few hours later a purgative enema. At the end of about three weeks get the patient up. If a radical cure has not been attempted, apply a pad and a spica bandage to the groin, and later a truss. A truss should not be worn if a radical cure has been made.

Mortality.—Cases of strangulated hernia irreducible by taxis will practically all die without operation. The mortality following operation is large; it is not due to operation, but is due to the condition, and is due particularly to delay in operating or to forcible antecedent taxis. Sultan, from a total of 1429 herniotomies, estimates the mortality at 20.7 per cent. Estimating the mortality according to the time of strangulation, Henggeler reaches the following conclusions: The mortality of cases operated upon "the first day after the strangulation is 8.09 per cent.; during the second day, 22.2 per cent.; during the third day, 45.5 per cent.; during the fourth day, 60 per cent." ("Atlas and Epitome of Abdomianl Hernias," by Dr. George Sultan. Translated and edited by Wm. B. Coley, M. D.). The mortality in children is smaller than in adults. In Coley's 12 cases of children under two years of age there was not a death.

Fig. 766.—Double inguinal rupture.

Hernia in Childhood.—Hernia is extremely common in children, but it is an interesting fact that if one conducts a careful investigation of hernia in adults, it will be found that but 5 or 6 per cent. of them have suffered from the hernia in childhood. This fact seems to demonstrate positively that the majority of cases of hernia in childhood are recovered from. A. J. Ochsner ("Jour. Am. Med. Assoc.," Dec. 22, 1900), in commenting upon the frequency of hernia in childhood, alludes to Malgaigne's statistics. Malgaigne estimated that during the first year of life 1 child in every 21 has hernia, and that this proportion is maintained until the age of six. Then it diminishes rapidly until the age of thirteen, at which age there is 1 hernia in every 77 children. It is, therefore, obvious that 75 per cent. of all herniæ in children of six years will heal spontaneously before the age of thirteen. Ochsner states that 95 per cent. of herniæ in children will be cured without operation. He points out that between the ages of thirteen and twenty hernia is fairly common among boys, but very rare among girls. The reason for the tendency to cure is somewhat uncertain. The view advocated by Thomas C. Martin is that, as the pelvis broadens, the parietal peritoneum enlarges. It does this at the expense of the mesentery, which is shortened, and the internal abdominal ring is displaced. In a very instructive analysis of this condition Ochsner shows that

in 25 per cent. of cases of hernia in childhood hereditary weakness exists; that the condition is commoner among the poorer classes than among the rich; that in many cases there is an undescended testicle; and that the chief cause is an excess of intra-abdominal pressure. This excess of intra-abdominal pressure may result from flatulent distention of the stomach and intestines, the product of bad feeding; constipation and straining; straining on urinating, due to the existence of phimosis; vomiting, or cough. He thinks that, as a rule, indigestion causes flatulence and pain; that the child cries; that this increases the pressure; that the mother then feeds it in order to keep it quiet, and that this makes it worse. Strangulation is rare in childhood.

Treatment.—Strangulated herniæ, irreducible herniæ, herniæ with very large rings, cases in which trusses fail, and cases associated with reducible hydrocele require operation (Ochsner). Most cases are curable without operation, the ring being guarded by a truss of rubber or a pad of lamb's wool. Ochsner believes that many cases can be cured by keeping the child recumbent, with the foot of the bed raised, from four to six weeks. If phimosis exists, it should be operated upon, and any other causative condition should be treated (cough, vomiting, constipation, flatulent indigestion, etc.). An umbilical hernia can usually be cured by the use of a cork. The cork should be 1 inch in diameter and $1\frac{1}{4}$ inches in length, and shaped like a cone. The smaller end is pushed into the ring and the cork is held in place by adhesive plaster. In two weeks a smaller cork must be used, and in six or eight weeks it can usually be dispensed with. Radical cure operations are seldom done before the age of four (see page 1136).

Varieties of Hernia.—*Direct inguinal herniæ* comprise less than 2 per cent. of cases of inguinal herniæ. In direct hernia the contents pass out through Hesselbach's triangle internal to the deep epigastric artery. They enter the inguinal canal low down, and pass outside the conjoined tendon or force the conjoined tendon before them or split through the tendon. They do not enter the scrotum. The neck of the sac is internal to the deep epigastric artery. The protrusion is globular in shape, unless it emerges around the edge of the tendon, in which case it is pear shaped. The coverings of this hernia, when it passes external to the conjoined tendon, are the same as those of an indirect inguinal hernia, except that the transversalis fascia instead of the infundibuliform process of the transversalis fascia is one of the layers. When a direct hernia pushes before it the conjoined tendon, its coverings are skin, superficial fascia, intercolumnar fascia, conjoined tendon, transversalis fascia, subserous tissue, and peritoneum.

In *indirect inguinal hernia* the contents pass through the internal abdominal ring external to Hesselbach's triangle and external to the deep epigastric artery. They pass down the inguinal canal and emerge from the external ring; and may or may not enter the scrotum or labium (*scrotal* or *labial hernia*). The protrusion is pear shaped. The neck of the sac is external to the deep epigastric artery. Its coverings are skin, superficial fascia, intercolumnar fascia, cremaster muscle, infundibuliform fascia, subserous tissue, and peritoneum.

Congenital inguinal hernia is a portion of bowel within an unclosed vaginal process. The bowel in congenital hernia has one layer of peritoneum in front of it. The testicle is posterior and below (Fig. 767, *b*). Always remember that bowel may not enter the sac of a congenital hernia for several months or longer after birth. Congenital hernia conceals or buries the testicle; acquired hernia does not. If a vaginal process, open above and closed below, contains a hernia, the condition is called *hernia into the funicular process* (Fig. 767, *c*).

If the funicular process is closed at the abdominal end, but not below, a hernia in a special sac may descend back of the vaginal tunic. This condition is known as *infantile hernia*. In infantile hernia there are three layers

of peritoneum in front of the bowel—the two layers of the vaginal tunic and the one layer of sac. The testicle is in front (Fig. 767, *d*).

If the tunica vaginalis is closed above and not below, and a hernia pushes down the vaginal process and causes it to double on itself, the condition is known as *encysted infantile hernia* (Fig. 767, *e*).

In *femoral hernia* the contents descend along the femoral canal to the inner side of the vein, and the neck of the sac is at the femoral ring. The neck of a femoral rupture is always external to the pubic spine; the neck of an inguinal rupture is always internal to the pubic spine. Femoral hernia contains omentum, but seldom intestine, except in strangulated cases. It used to be said that femoral hernia is never congenital. Russell and Coley show that it may be (see page 1133). The coverings of a femoral hernia are skin, superficial fascia, cribriform fascia, crural sheath, septum crurale, subserous tissue, and peritoneum.

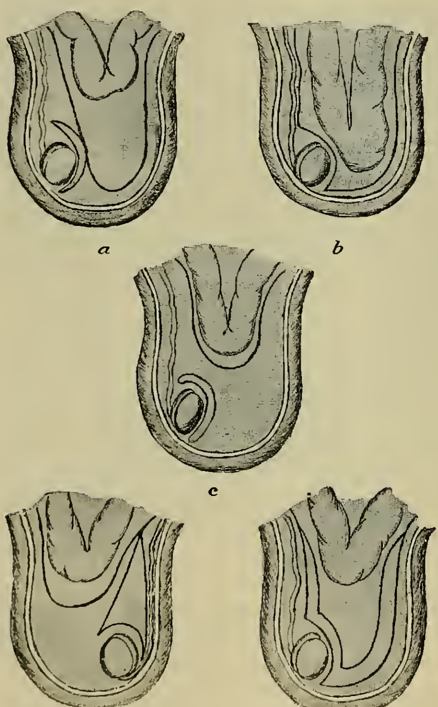

Fig. 767.—*a*, Scrotal hernia; *b*, congenital hernia; *c*, funicular hernia; *d*, infantile hernia; *e*, encysted hernia.

Occasionally a femoral hernia may pass in front of the vessels (*prevascular femoral hernia*). Moschchowitz operated upon such a case ("Annals of Surgery," June, 1912). A hernia may be external to the femoral artery (*Hesselbach's hernia*); may pass through an opening in Gimbernat's ligament (*Laugier's hernia*); may come down alongside of the femoral vein, but instead of emerging from the saphenous opening spread into the pectineus muscle (*Cloquet's hernia*).

Umbilical hernia may be congenital (the ventral plates having closed incompletely), infantile (the cicatrix of the umbilicus having stretched), or acquired.

Ventral hernia is a protrusion through any part of the anterior abdominal wall except at the umbilical or inguinal regions. A ventral hernia may be median (*hernia of the linea alba*) or lateral. The treatment is radical operation.

Epigastric hernia is a form of ventral hernia. In this condition there is a protrusion of the peritoneum in the space bounded by the ensiform cartilage, the ribs, and the umbilicus. The sac of peritoneum may be empty, may contain omentum, or omentum and bowel. The stomach very rarely passes into the sac. The protrusion is usually, but not invariably, through the linea alba. The condition may be due to a congenital gap in the transversalis fascia or to the growth of a fat hernia. This condition may cause abdominal pain, epigastric pain, nausea and vomiting after eating or effort, and, according to Farrar Cobb ("Annals of Surgery," Jan., 1912), chronic diarrhea.

Cecal hernia is very uncommon in women. It may be either congenital, infantile, or acquired. If a vaginal process is open the cecum may readily enter it, it may be drawn in by the plica vascularis as the testicle descends

(Wrisberg), it may be drawn in by a descending testicle the posterior peritoneum over which has formed adhesions to the cecum. Most acquired cecal herniæ are preceded and caused by hernia of the small gut, but they may occur alone. In the simple form the cecum is completely covered by a coat of peritoneum and lies within the sac. Usually there is a complete surrounding sac, but sometimes the sac only partially covers the cecum lying in front and to the inner side. In these cases the cecum is on the posterior and external aspect of the wall of the sac. The appendix may be in the sac, outside of the sac, or part may be within and part without. If the sac is incomplete, it means that we have one of the 18 per cent. of cases in which the cecum is not completely covered with peritoneum. A cecal hernia may be and usually is right inguinal, but may be right femoral, left inguinal, or left femoral. It is most common in advanced life and is frequently irreducible.

Hernia of the appendix may occur alone, and Merigot de Treigney collected 22 cases of it ("Thèse de Paris," 1887). In 17 the hernia was inguinal; in 5 it was femoral. I operated upon a case of appendicitis in which the inflamed appendix was the sole occupant of an incomplete right inguinal hernia sac. In some cases the appendix accompanies the cecum into a hernia.

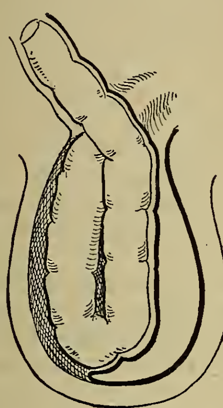

Fig. 768.—The large intestine behind the peritoneum (Weir).

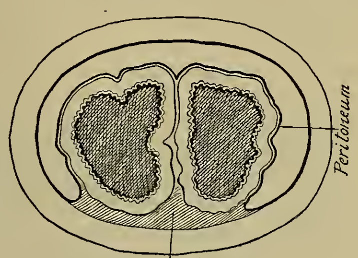

Fig. 769.—The retroperitoneal large intestine in a cross-section of the hernia with its incomplete sac (Weir).

Adherent hernia of the large intestine (*sliding hernia*) is a condition first described by Scarpa, in which the sac of a right-sided hernia contains ascending colon; of a left-sided hernia, descending colon. The sac is complete on the anterior, but apparently absent on the posterolateral aspect, where the bowel seems as though fused to it. This condition has often been called "hernia with incomplete sac." A commonly accepted theory is that because of looseness of the peritoneum of the iliac region a portion of the large bowel slides into the hernia. In such a case the posterolateral aspect of the sac is absent (Figs. 768 and 769). In a right-sided condition the descending bowel carries with it into the scrotum a fold of loosened peritoneum, just as in the descent of the testis (Weir, in "Med. Record," Feb. 24, 1900). Sliding hernia of the ascending colon is wrongly called sliding hernia of the cecum. In most cases of sliding hernia of the left side the descending colon is dragged into a preëxisting hernia sac containing small bowel, omentum, or both. The large bowel is covered with peritoneum except posteriorly, where the mesocolon is attached. This form is nearly always irreducible and occurs particularly in elderly men. In another group of cases the large bowel makes a direct inguinal hernia and the sac is limited to the anterior surface of the protruded gut.

In this edition I have adopted the name "adherent hernia" instead of "sliding hernia." L. J. Ransohoff ("Annals of Surgery," August, 1912) seems to

demonstrate that the condition is not due to sliding of the peritoneum, and hence is not a sliding hernia; that an incomplete sac is a secondary process, the sac having been complete in its incipiency, but obliterated posteriorly "by secondary adhesions of the embryonic type." The immobile loop of intestine in the sac was originally mobile; "the hernia is primary, the adhesions secondary" (Ransohoff, "Annals of Surgery," Aug., 1912).

In *properitoneal hernia* the sac is between the peritoneum and transversalis fascia. The form of hernia is sometimes produced by making taxis on an inguinal hernia, when the internal ring is small or is blocked by an undescended testicle. In properitoneal inguinal hernia, which is the most common form, there are two sacs, one in the scrotum, the other parallel with Poupart's ligament, and as one sac is emptied, the other distends (Breiter, of Zürich).

In *interstitial* or *interparietal inguinal hernia* the hernia sac is between the transversalis muscle and fascia, or between the external and internal oblique muscles, or in the midst of the fibers of the internal oblique muscle, or between the external oblique muscle and the transversalis fascia, the internal oblique and transversalis muscles being pushed aside (Sultan's "Atlas of Abdominal Hernias").

In *superficial inguinal hernia* the sac is between the aponeurosis of the external oblique muscle and the superficial fascia. This variety of hernia is always congenital and the testicle is invariably misplaced.

Obturator hernia passes through the obturator membrane or the obturator canal, and is felt below the horizontal ramus of the pubes, internal to the femoral vessels. The obturator nerve is pressed upon and pain arises in its trajectory.

Lumbar hernia is a very rare condition. It may be congenital, traumatic, or spontaneous, and may follow a lumbar abscess. Braacz collected 68 cases. It occurs through the triangle of Petit, or just below the twelfth rib through the superior lumbar triangle, or through a congenital defect in the aponeurosis of the latissimus dorsi muscle, or through a defect near the triangle of Petit (Dowd, in "Annals of Surgery," Feb., 1907). A lumbar hernia may be present at the edge of or through the quadratus lumborum muscles.

The *triangle of Petit* is bounded in front by the external oblique, behind by the latissimus dorsi, below by the iliac crest, and its floor is formed by the internal oblique. The *superior lumbar* triangle (of Grynfelt and Lesshaft) is bounded anteriorly by the external oblique, posteriorly by the iliocostal muscle, above by the serratus posticus inferior and the end of the twelfth rib, and below by the internal oblique. The latissimus dorsi overlies it.

Sciatic or *gluteal hernia* passes through the great sacrosciatic foramen, above or below the pyriformis muscle, or through the lesser sacrosciatic foramen.

Pudendal hernia protrudes into the lower part of the labium, the bowel having descended between the ischial ramus and the vagina.

Perineal hernia presents in the perineum, between the rectum and the prostate gland or between the rectum and the vagina.

Internal, retroperitoneal, or *intra-abdominal herniæ* include hernia into the *foramen of Winslow,* hernia into the *retroduodenal fossæ,* the *retrocecal fossæ,* and the *intersigmoid fossa* (see page 981).

Vaginal hernia is associated with uterine prolapse or ensues upon destruction of the vaginal wall.

Richter's hernia (partial enterocele or hernia of the intestinal wall, Fig. 770, A) was described by Richter in 1778. He called it "the small rupture." It occurs only in adults and is most common in women. It is the catching of a portion of the circumference of the bowel, usually a portion of the lower part of the ileum. It is usually femoral, but may be inguinal, and even epigastric or

obturator. It arises usually in an old, reducible hernia (Royal Hamilton Fowler, "Am. Jour. Surg.," Jan., 1912). Some cases are due to adhesions. It may be due to truss pressure on an incompletely reduced hernia (Fowler, Ibid.). Strangulation of a partial enterocele may not completely close the lumen of the gut. There may not be stercoraceous vomiting or absolute constipation, and the protrusion is barely perceptible or cannot be palpated.

Littré's hernia is hernia of Meckel's diverticulum (Fig. 770, B). It was described by Littré in 1700. This diverticulum is the persistent vitelline duct and comes off from the ileum from 12 to 36 inches above the ileocecal valve. It arises from the convex side of the gut and rarely has a mesentery (see pages 982 and 988).

Rokitansky's diverticular herniæ are due to separation of the muscular fibers of the bowel, permitting the sacculation of mucous membrane and peritoneum. These false diverticula may be no larger than peas or may be larger than walnuts, and there may be scores of them in one patient. They may produce no symptoms or may lead to peritonitis, abscess about the bowel, perforation, or to symptoms of intestinal obstruction.

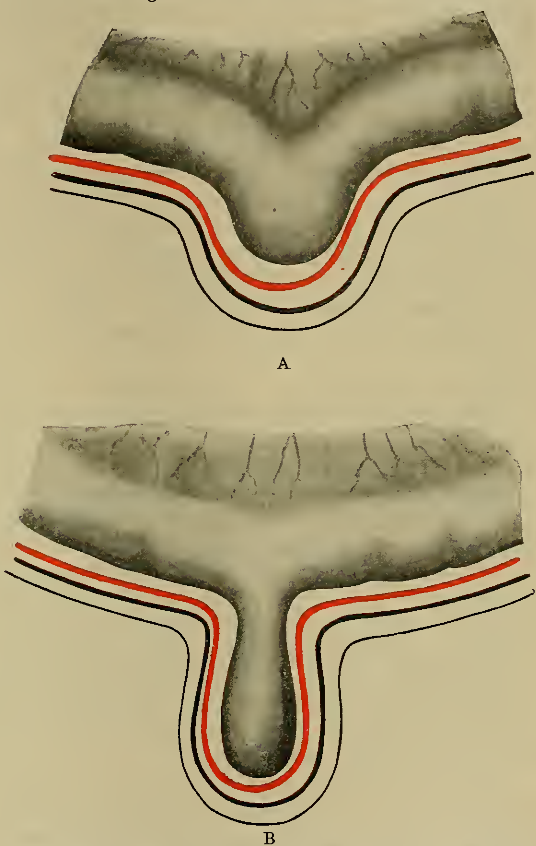

Fig. 770.—A, Diagrammatic representation of Richter's hernia of intestinal wall. B, Diagrammatic representation of Littré's hernia, which is a hernia of Meckel's diverticulum (Sultan).

Hernia of the Bladder.—This is a protrusion of a portion of the bladder wall through a hernial opening. Eggenberger adds 110 cases to Brunner's 182 cases, a total of 292 cases ("Deutsch. Zeitschr. f. Chir.," Oct., 1908). Most cases are instances of false hernia, there being no sac of peritoneum. The protrusion may or may not be covered with peritoneum, and in most cases it is not so covered, but lies by the side of a hernial sac and not inside of it. Brunner's table shows only 5 cases of true bladder hernia, that is, of intraperitoneal hernia. It is most frequently met with in the inguinal region. Brunner describes three forms: (1) Entirely without a peritoneal covering (extraperitoneal); (2) partly covered with peritoneum (paraperitoneal—the commonest form); (3) completely covered with peritoneum (intraperitoneal). The bladder may constitute the hernia, or there may be an ordinary hernia and also a cystocele. In an inguinal hernia the bladder will be internal and somewhat behind the other constituent parts of the protrusion. Hernia of the bladder is much more common in men than in women.

A hernia of the bladder may become strangulated. In some cases a diagnosis of hernia of the bladder can be made by the fact that the protrusion lessens in size when the patient micturates, and increases in size as urine gathers or when the bladder is injected with fluid. The treatment should be operative. When the bladder is exposed it is replaced if possible without resection of a portion.

Diaphragmatic Hernia.—The majority of cases are congenital and in 90 per cent. of them there is no sac. The hernia may pass through a natural opening or through a gap due to congenital defect. The hernia is most common on the left side, and the stomach is the organ which is most often found in the hernia, but the colon, the omentum, the small intestine, the spleen, liver, duodenum, cecum, pancreas, or kidney may be found (Cranwell, "Rev. de Chir.," 1908, No. 1). Violent traumatism may be the cause. When the stomach passes suddenly through the left side of the diaphragm there will be dyspnea, cyanosis, displacement of the heart to the right, pain in the upper abdomen, thirst, and in most cases rapid death. When the stomach or intestine has entered the left side of the thorax, there is a tympanitic note on percussing over that area of the thorax, the heart is displaced to the right, and the side of the chest is unduly prominent. The upper border of the tympanitic area does not move with respiration. There are no breath sounds audible over the tympanitic area, but gurgling is heard. In 250 cases of traumatic diaphragmatic hernia collected by Leichtenstern the diagnosis was made before death in but 5 cases. The *x*-rays are of value in diagnosis, especially if the stomach is in the hernia. Strangulation of a diaphragmatic hernia produces severe pain in the upper abdomen, violent vomiting, constipation, boat-shaped abdomen, great thirst, rapid wasting, and the excretion of a very small amount of urea (Mackenzie and Battle, "Lancet," Dec. 7, 1901). Diaphragmatic hernia may be confused with *eventration of the diaphragm*, an unnaturally high position of the left half of the diaphragm, with ascent of the viscera of the abdomen, especially the stomach. It was first described by Petit in 1790. Sailer and Rhein reported a case and collected 12 others ("Am. Jour. Med. Sciences," April, 1905). The physical signs of eventration are practically identical with those of diaphragmatic hernia, except that in the former the upper border of the tympany moves on respiration.

Treatment.—Open the belly for exploration. If a hernia is found, return it to the abdomen; open the chest and suture the diaphragm from above (transpleural suturing). Mackenzie and Battle, Mikulicz, Humbert, and others have operated for this condition.

Hernia of the Ovary.—The ovary, because of failure of descent, may remain in the lumbar region. It may pass into the inguinal canal or labium majus (inguinal hernia); to the gluteal region (gluteal hernia); to the region of the obturator foramen (obturator hernia); or to the front of the abdomen (ventral hernia). In congenital inguinal hernia there may be ovary alone, or ovary, tube, omentum, and even part of a bicornate uterus (Garrigues). It is impossible to restore a congenital hernia. Acquired hernia may follow a fall and sometimes it can be restored. A femoral or crural ovarian hernia, a condition in which the ovary passes to the front of the thigh below Poupart's ligament, is never congenital. In some cases a herniated ovary can be returned within the abdomen. Any herniated ovary may inflame.

Treatment.—If the ovary can be restored, a truss will probably retain it, but even in such a case operative cure is better. If it cannot be restored or if it is painful or undesirable to wear a truss, operation must be done. Expose the ovary, return it to the belly if healthy, and do a radical cure of the hernia. In some conditions of disease remove the ovary.

Hernia of the Uterus.—This condition is a surgical curiosity, but a few

cases have been reported (John Howard Jopson's case in "Annals of Surgery," July, 1904). The hernia may be umbilical, ventral, inguinal, or femoral. Hernia of the unimpregnated womb may be congenital or acquired; impregnation may occur when the uterus is herniated, or an impregnated uterus may pass into a preëxisting hernia sac. If a herniated uterus becomes impregnated or if an impregnated uterus becomes herniated, pregnancy may go on to term. Multiple pregnancies predispose to uterine hernia. Ovarian hernia may precede uterine hernia, or hernia of omentum adherent to the uterus may pull that organ into the sac. In many cases congenital anomalies have been found to exist (bicornate uterus, rudimentary uterus, shortness of the round ligament, imperforate vagina, etc.). A hernia of the uterus enlarges and becomes painful during menstruation, and a vaginal examination shows that the uterus is absent from its normal position and that the direction of the cervix and vagina are abnormal (Jopson, Ibid.). A uterine sound cannot be passed at all or can be passed with great difficulty. The hernia is hard and probably pyriform. If impregnation occurs, there are the ordinary signs of pregnancy and progressive enlargement of the hernia.

Treatment.—Expose the mass by incision. If conditions justify such a course, return the uterus and adnexa, if they are present (one or both ovaries and tubes may be present), to the abdomen and do a radical cure. If the uterus is infected, remove it. Jopson in his case removed the uterus and right ovary and fastened the uterine stump into the wound.

XXIX. DISEASES AND INJURIES OF THE RECTUM AND ANUS

Teratoids and Dermoids Associated with the Sacrococcygeal Region.—In the sacrococcygeal region there are many opportunities for developmental error. In this region the caudal end of the primitive streak must undergo evolution and involution, the neurenteric canal must form and disappear, the anus must be formed, the posterior fissure must close, the sacrum and coccyx must develop, and various other processes must go on correctly and uniformly if complete development is to be obtained. As Coplin puts it: "Perfect evolution of the tissues embraced in this part of the body is beset by many narrow escapes" ("Publications from the Laboratories of Jefferson Med. College Hospital," 1906, vol. iii). Fissures and clefts may fail to close, fragments from one blastodermic layer may be lodged in another layer, groups of cells may be sequestered, closing clefts may include tissue elements, and parts that should normally atrophy may do so late or not at all.

In order to understand teratomata and dermoids arising in the rectal region we must recall some facts of development.

Early in embryonic life the central canal of the spinal cord and the alimentary canal are continuous around the caudal end of the notochord by a communicating path called the neurenteric canal.

When the anal pit undergoes invagination it meets the gut considerably in front of the region where the neurenteric canal joins the gut. The portion of intestine between the anus and the opening of the neurenteric canal is called the *postanal* gut. The postanal gut disappears during normal development. If it persists it causes tumor formation.

The congenital tumors of the sacrococcygeal region are: (1) Tumors of the postanal gut; (2) dermoids back of the rectum; (3) rectal dermoids.

According to Bland-Sutton, tumors of the postanal gut "are composed of closed vesicles lined with glandular epithelium and contain glue-like fluid" ("Tumors, Innocent and Malignant," by Sir J. Bland-Sutton). These tumors grow to a large size.

Dermoids back of the rectum often contain teeth, may attain large size, are apt to mount up behind the peritoneum, and may rupture and form a fistula. I helped Prof. Keen operate on such a case. The skin over the mass showed a growth of hair, there was a gap or cleft in the sacrum, and through this there was a clear passage from the rectum to the skin. This sinus closely resembled the trachea in structure.

Dermoids occasionally grow from the mucous membrane of the rectum and are apt to contain an abundant growth of hair.

Examination of the Anus and Rectum.—There are four positions in which we may place the patient for rectal examination, the one to be selected depending upon the probable local difficulty. These positions are the left lateral prone, the knee-chest, the exaggerated lithotomy, and the squatting position. The knee-chest position is desirable if the sigmoidoscope is to be used. A commonly employed position is the *left lateral prone position of Sims*, in which the patient lies on the left side, the chest on the table, the left arm behind the back, the knees drawn up, and the pelvis elevated on a hard pillow.

Very stout people should be placed in the *knee-chest position* or *exaggerated lithotomy position*, as the rectum cannot be seen when they lie on the side.

A *squatting position*, when the patient is placed as though on a commode, is best adapted to cases of prolapse and hemorrhoids. It is also used to bring within the range of the finger strictures or new growths that in the other attitudes would be beyond digital reach.

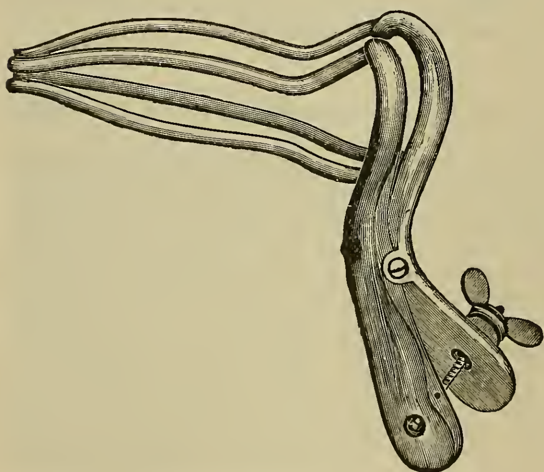

Fig. 771.—Mathews's self-retaining rectal speculum.

Sometimes the surgeon is able to pass a sigmoidoscope upon a patient in the exaggerated lithotomy position when it has been found impossible to carry the instrument high enough with the patient in any other position.

While making a rectal examination the patient should have no constriction about the abdomen, such as corsets, bandages, or tight clothing.

It is important that the first examination be made when no cathartics or enemata have been administered, so that the condition of the excretions and secretions may be noted. By such first examination pus, blood, mucus, or inspissated fecal matter if present may be seen, and from their varying characteristics, quantities, and locations inferences as to causation may be drawn. After these observations have been made an enema should be given and the anus and rectum be well cleansed. When the parts have been cleaned and the bowel washed out the anus is carefully inspected, the anal folds being opened during the process. By inspection the surgeon can notice the external opening of a fistula, external piles, protruding internal piles, mixed piles, pruritus, discharge from the rectum, eczema, fissure, tumor, ulcer, condylomata, abscess, whether or not the anus is retracted and funnel-shaped or protruding, or if there be parasites on the anal hairs.

Next the thumbs should be placed on either side of the anus and gently separated; this maneuver, aided by a bearing down effort on the part of the

patient, will often cause piles to protrude, exhibit fissures and polypi, and reveal the condition of the mucocutaneous border.

Next, a digital examination of the rectum is made. The nail of the index-finger is filled with soap and the finger is oiled or, better, is covered with a rubber finger-tip which is oiled. The digit is gently inserted through the sphincter, the patient being asked to strain lightly while it is passing. The finger is inserted with a gentle boring motion and is pointed toward the umbilicus until the sphincter is passed. A digital examination enables the surgeon to detect an ulcer, a polypus, a tumor, a stricture, and to determine certain points regarding the condition of the prostate in the male and the uterus in the female. Non-indurated piles cannot be detected by the finger. A speculum will be needed to discover them if they are not protruding.

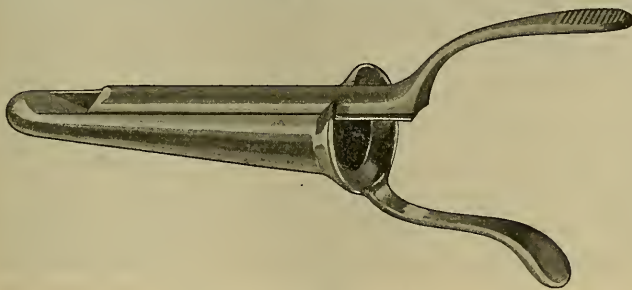

Fig. 772.—Brinkerhoff's speculum.

Next, in some cases, the rectum must be examined by means of a speculum. It is not often necessary to give ether. Mathews's speculum (Fig. 771) is very serviceable. Sims's duck-bill speculum is a valuable instrument for certain cases. The speculum is warmed, oiled, and slowly introduced. It is first directed toward the umbilicus, and when it passes the sphincter its direction is gradually altered until it is toward the promontory of the sacrum. Illumination is obtained by direct sunlight or by a forehead mirror and an electric light. This examination will extend, confirm, or disprove the findings of the digital examination; ulcers, hemorrhoids, and malignant growths can be carefully examined, and the condition of the rectal mucous membrane can be thoroughly investigated.

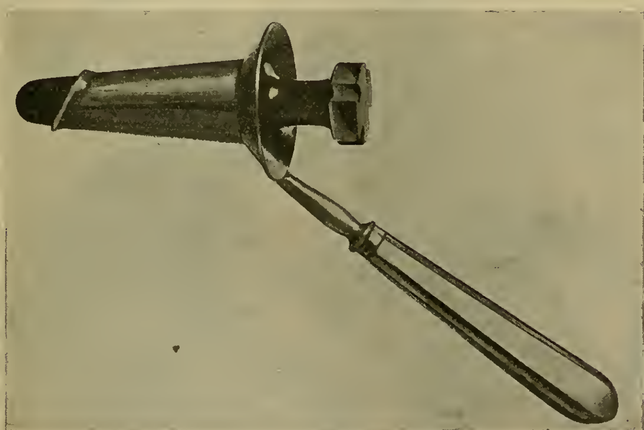

Fig. 773.—Martin's speculum.

Marion Sims in 1845 demonstrated the ballooning of the vagina by atmospheric pressure, and in 1870 Van Buren applied this method to the rectum. Kelly in 1895 put forth his straight tubes and described in detail the methods

Fig. 774.—Cook's operating speculum.

and advantages of examination by them, and the great diagnostic value of ballooning the rectum. Kelly's method of examination is shown in Fig. 775. The tubes are shown in Fig. 776. It is not necessary to give ether. The

Fig. 775.—Examination of the rectum by reflected light (Kelly).

patient is placed in the knee-chest position. A tube containing an obturator is well greased with vaselin. "The buttocks are drawn apart, and the blunt end of the obturator is laid on the anus, which is also coated with

vaselin. The direction of the instrument should be first downward and forward, and, when the sphincter is well passed, up under the sacral promon-

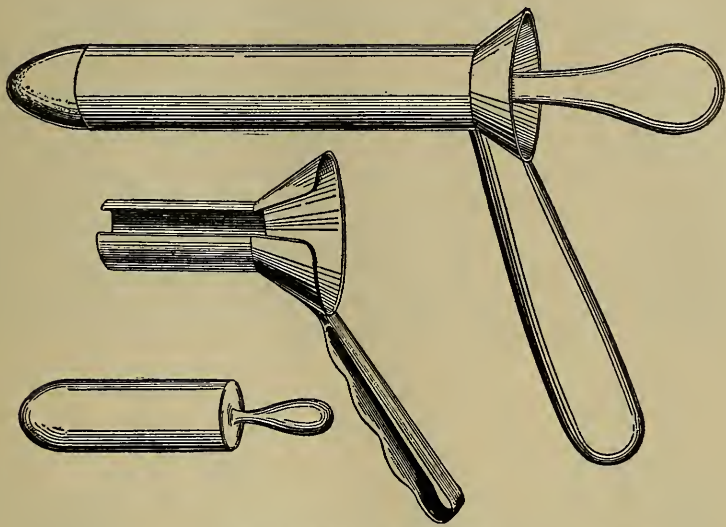

Fig. 776.—Kelly's rectal specula.

tory. The moment the speculum clears the sphincter ani and the obturator is withdrawn, air rushes in audibly and distends the bowel." When the entering instrument is pressed gently against the sphincter a sharp muscular contraction ensues. If the instrument is gently and slightly withdrawn, relaxation occurs, and the moment of relaxation may be seized to make an entry. An entry so made is rapid and unresisted. The bowel being distended with air, the mucous membrane is plainly seen as the tube is slowly withdrawn and the electric light is reflected into the speculum by a forehead mirror. The normal mucous membrane is dull red, like the nasal mucosa, and the blood-vessels are plainly distinguishable. The Kelly tube must be used with great care, as harm may be done by it, and the longest tube should be used only in exceptional cases.

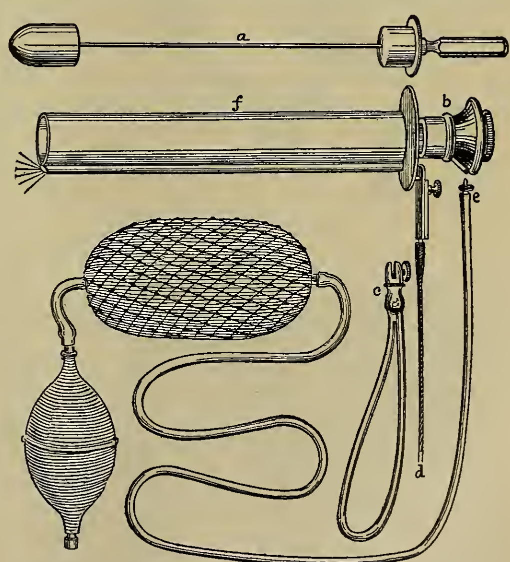

Fig. 777.—Tuttle's pneumatic proctoscope: *a*, Obturator; *b*, plug with glass window closing end of tube; *c*, handle; *d*, cords connecting instrument with battery; *e*, inflating apparatus; *f*, main tube of proctoscope.

I use with the greatest satisfaction James P. Tuttle's pneumatic proctoscope (Fig. 777). Dr. Tuttle describes it as follows ("Diseases of the

Anus, Rectum, and Colon"): "This instrument is composed of a large cylinder (*f*), into one part of the circumference of which is fitted a small metallic tube closed by a flint-glass bulb at its distal end. The electric lamp (*d*) is fitted upon a long metallic stem, and carried through the small cylinder to the end of the instrument, as shown in the illustration. The proctoscope is introduced through the anus with the obturator (*a*) in position. As soon as the internal sphincter is passed this obturator is withdrawn and the bayonet-fitting plug (*b*), which contains either a plain glass window or a lens focused to the length of the instrument to be used, is inserted in the proximal end of the instrument. This plug is ground to fit air-tight and thus closes the instrument perfectly. The plug being inserted in the tube, a very slight pressure upon the hand-bulb will cause inflation of the rectal ampulla to such an extent that the whole rectum can be observed and the instrument can be carried up to the promontory of the sacrum without coming in contact with the rectal wall. Further dilatation will show the direction of the canal leading into the sigmoid, and, by a little care in manipulating the instrument and keeping

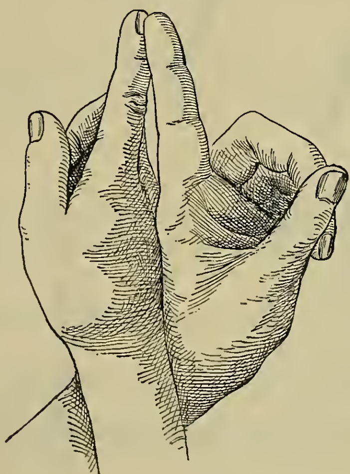

Fig. 778.

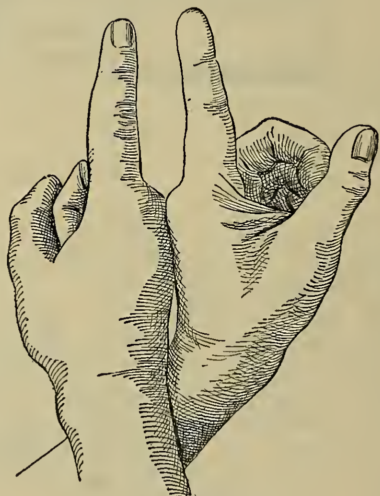

Fig. 779.

Figs. 778, 779.—A new and simple method of proctoscopy (Thomas C. Martin).

the gut well dilated in advance, it can be carried up into this portion of the intestine without the least traumatism of the parts. If any fecal matter obscures the light by being massed or smeared over the glass bulb, the plug can be removed, and a pledget of cotton, introduced with a long dressing forceps, will wipe this off, so that the plug can be reintroduced and the examination continued with very slight delay or inconvenience. The adjustable handle (*c*) fits on the rim of the instrument and thus converts it into a Kelly tube. This instrument is operated with an ordinary dry battery of four cells. It is better, however, to have a battery with six cells, as it will not require being recharged so frequently." All the air must be allowed to escape before the instrument is withdrawn, otherwise colic may develop.

If an anesthetized patient is placed in the knee-chest position, the sphincter can be stretched by the fingers, and the rectum will distend with air and can be easily examined. The fingers are introduced as suggested by Martin (Fig. 778) and the rectum becomes visible when they are separated (Fig. 779).

Passage of Rectal Tubes.—Some have asserted that soft tubes can be passed from the anus through the sigmoid. I do not believe this can be done in a normal rectum, it matters not in what position the patient is placed, and whether or not fluid flows from the tube during its introduction. A soft tube always coils up after it has ascended 6 or 7 inches. In a number of laparotomies, desiring to locate the rectum, I have had an assistant pass a rubber tube. It would never ascend above the rectal dome unless I aided it with a hand in the belly, when it could be gotten through the sigmoid. Fortunately it is not necessary to give high enemas, as fluid introduced into the rectum is carried back to the sigmoid. If we wish fluid retained, attempts to pass the tube high up will cause irritation, and irritation will lead to expulsion.

Foreign Bodies in the Rectum.—It is not at all unusual for hard, undigested articles taken with the food to lodge in the rectum. They can usually be removed through a speculum by means of forceps. In some cases ether must be given and the sphincter stretched; in others, the sphincter must be divided. Sometimes large bodies are voluntarily inserted and the individual is unable to remove them. Lewis H. Adler ("Am. Med.," July 20, 1901) removed the valve of a steam radiator pipe from the rectum. The small end was $1\frac{1}{2}$ inches in diameter; the large end was $2\frac{1}{2}$ inches in diameter. The patient had been in the habit of introducing it frequently and removing it with a hook of galvanized iron wire. A. Marmaduke Sheild ("Lancet," Oct. 12, 1901) reports the case of a man sixty years of age who forced a gallipot into the rectum. The pot was $2\frac{1}{2}$ inches in diameter and $2\frac{3}{4}$ inches in height. The patient broke it trying to get it out. Sheild incised the sphincter from behind and removed the article by means of obstetric forceps.

If the foreign body is soft, as an apple or a potato, a hole should be bored through to allow the air to pass and thus relieve the suction. It can then be lifted out. If the body is of wood, screw in a gimlet; if of metal, cut with strong forceps; if of glass, remove as Sheild did the gallipot. If the article is rough or has sharp edges, pack gauze all around it as a first step to protect the rectal walls. In a case in which a boar's tail had been introduced, large end first, the holding back of the bristles was overcome by sliding over it a large-sized rubber catheter.

Foreign bodies may escape into the sigmoid and necessitate a laparotomy. They may also cause periproctic inflammation.

A remarkable series of cases of foreign bodies in the rectum may be found in "Anomalies and Curiosities of Medicine," by George M. Gould and Walter L. Pyle.

Wounds and Injuries of the Rectum.—These accidents may result from fractures of the pelvis, most often from fractures of the sacrum, from the improper use of enema syringe nozzles or tips, from gunshot-wounds, stab-wounds, foreign bodies introduced by the patient, and, rarely, from digital examinations. The important points to consider in these wounds are whether or not there is penetration of the entire rectal wall, involvement of the perirectal tissues, or peritoneum. Slight wounds involving only the mucous membrane are frequently very grave from the fact that the hemorrhage is constant into the rectum, filling back into the sigmoid, often followed by collapse before or when the blood is voided. The investigations in these cases should always be thorough and by both digital and visual examination, for exact diagnosis is of the utmost importance.

If the peritoneum has been lacerated, laparotomy should be performed at once, the wound in the bowel repaired, the peritoneal cavity cleansed and drained, and the Murphy treatment for general peritonitis instituted (see page 1025). If the laceration involves the perirectal tissues but not the peritoneum, cut down on the side of the bowel that is injured and make free drainage. In the event of very extensive injuries to the perirectal tissues the

question of inguinal colostomy should be considered. If the wound involves only the mucous or submucous coats, dilate the sphincter, arrest hemorrhage by suture or ligature, and follow by irrigation.

Inflammation of the Rectum and Sigmoid (Proctitis and Sigmoiditis).—These conditions may be acute or chronic, simple or specific. The simple forms are acute catarrhal, atrophic catarrhal, and hypertrophic catarrhal. The specific forms are gonorrheal catarrhal, diphtheritic catarrhal, erysipelatous catarrhal, dysenteric catarrhal, and syphilitic catarrhal (Tuttle, "Diseases of the Anus, Rectum, and Colon").

Acute Inflammation.—Acute catarrhal inflammation may be caused by that class of incidents which are apt to be followed by ordinary catarrh of the respiratory passages and, in addition, errors of diet or sudden change of temperature, as sitting on a cold seat when overheated. The onset is sudden, with chill, general malaise, pain and discomfort locally, and slight fever. There is a sense of fulness and weight, with often a burning sensation referred to the rectum, and at times tenesmus with frequent desire to go to stool. Pain radiates to adjacent parts and there is bladder irritability. Patients usually prefer to be in the recumbent posture.

There will be at first a thin fecal discharge followed by mucus tinged with blood. Ulceration soon supervenes. The parts are hot, dry, and swollen in the first stages and digital examination is very painful. Later the parts are slimy and the mucous membrane is covered with tenacious mucus and pus.

Treatment.—First remove irritating intestinal contents and reduce engorgement by lavage and saline cathartics, followed, if early in the case, by irrigations of cold water; if later, by hot water. A useful medicated irrigation is a 5 to 10 per cent. solution of the aqueous extract of krameria.

Chronic Inflammation.—In chronic proctitis and sigmoiditis the symptoms are similar to those present in the acute forms of the inflammation, but less severe in character. In addition there is increased secretion of mucus, flatulence, and marked general intestinal disturbance.

The mucous membrane is soft, doughy, and thickened, which condition palpably reduces the caliber of the gut. Through the speculum the membrane is seen to be edematous, pale, and covered with secretion. It bulges into the aperture of the speculum and does not bleed easily.

Treatment is hygienic and dietetic, with antiseptic and astringent irrigations.

Atrophic Inflammation.—The atrophic variety of inflammation is characterized by long-continued constipation, dry stools covered with blood and mucus. There is such pain on expulsion of feces as to simulate in many cases fissure of the anus. The mucous membrane of the anus ruptures easily when stretched during examination. It is bright red and shiny, does not fill the aperture of the speculum, and bleeds readily. Ulceration is common and hemorrhoids are a frequent complication.

Treatment is local and general. Locally, use a dilute solution of nitrate of silver (1:2000), hydrastis (2 per cent. solution), or ichthyol, applied after the rectum is emptied. General treatment is hygienic and dietetic.

Peri-anal and Perirectal Inflammations.—These are of two classes —circumscribed inflammations or abscesses and diffuse inflammations that always develop pus. The circumscribed variety may be either superficial or deep. The superficial variety again may be tegmentary, subtegmentary, or *ischiorectal.* The deep variety may be of two forms—retrorectal or superior pelvirectal. It is important to note that right-sided superior pelvirectal abscess may be confounded with appendicitis.

The diffuse perirectal inflammations are variously classified, but the particular names refer only to the degree of the inflammatory process, which may vary from ordinary suppuration to gangrene.

These inflammations travel in the line of least resistance, which is upward, and more often burst into the bowel than externally. They may follow chilling of the region or external traumatisms, may be caused by perforation of the rectum by hard fecal masses, or by the direct passage of bacteria into the fossa through a fissure, an ulcer, or an ulcerated pile. They may be either acute or tuberculous. In many cases the process is at first tuberculous, and secondary infection with pyogenic bacteria takes place.

The **symptoms** are nearly identical with those of abscess elsewhere, the swelling, however, being brawny, and it being difficult or impossible to detect fluctuation. Pain in the groins is often complained of, and there may be enlarged glands in these regions. Abscesses commonly result in fistula, and a patient should be warned of this tendency before operation is performed. Superior pelvirectal abscesses generally follow inflammation of some pelvic organ, viz.: tubes, urethra, prostate, and the symptoms are mainly those of such an inflammatory condition. The usual tendency of the pus is to burrow upward. The presence of pus is indicated by the symptoms of suppurative toxemia, which sometimes simulate typhoid fever.

The **treatment** is instant incision. The patient, after having been anesthetized, is placed in the lithotomy position. The cut should be parallel to the fibers of the external sphincter and well outside of the muscle and longer than the inflamed area. When this incision is made, the finger should be introduced to break down the necrotic septa of cellular tissue. Then an incision should be made from the middle of the first cut radiating outward and opening any pockets external to the original focus. Then the free edges of the cuts are pared away, sacrificing all involved tissue. The wound is irrigated, the sphincter dilated, and the cavity packed with iodoform gauze. If a fistula is found opening into the rectum, it is not to be operated on until after the wound is nearly healed, only a small fistulous tract remaining.

In cases of superior pelvirectal abscess the incision should be made at right angles to the fibers of the levator ani muscle to facilitate drainage. In these cases tubal drainage is used.

Imperforate Anus.—There are two forms of this condition. In one form the rectum empties into the bladder, vagina, or urethra. In the other form there is no rectal opening either upon the surface of the body or in the genito-urinary organs. The diagnosis is usually at once apparent, except in cases in which the anus looks normal, when the diagnosis will often not be made until symptoms of obstruction arise.

Treatment.—If the rectum bulges when the child cries, open into it with a knife and keep the opening patent by inserting a plug of iodoform gauze. In cases in which the rectum is more deeply seated, a catheter is introduced into the bladder, an incision is made from the anus to the coccyx, the rectum is sought for, and when found is sewed to the anus and is incised. Keen, the author, and others have performed Kraske's sacral resection, pulling down the rectum to the anal margin, sewing it there, and incising the occluded anus. If the rectum cannot be found or cannot be pulled down, an artificial anus must be made.

Fistula in ano is the track of an unhealed abscess. An abscess in the anal region is apt to refuse to heal because of the constant movement of the parts (produced by respiration, coughing, the passage of gas, defecation, etc.). The passage of feces along the tract will keep a fistula open. If a tuberculous ulcer perforates a tuberculous sinus forms, and a tuberculous sinus is also apt to follow a cold abscess of the ischiorectal fossa. Fistula is often associated with phthisis pulmonalis, and is not unusually linked with piles, cancer, or stricture.

There are three varieties of fistula—the blind external (Fig. 780, A), the blind internal (Fig. 780, B), and the complete (Fig. 780, C). The *external*

opening is usually near the anus, but may be far away, and there may be only one pathway or there may be several sinuses and openings. In a healthy individual the external orifice is small and a mass of granulations sprouts from it. In a tuberculous fistula the external orifice is large and irregular, with thin and undermined edges, shows no granulations, extrudes small quantities of sanious pus, and the skin about it is purple and congested. In a fistula following an anal abscess the *internal* opening is just above the anus, between the two sphincters. In fistula following an ischiorectal abscess the internal opening is usually near the anus, but may in rare cases be above the internal sphincter. A sinus may run up under the mucous membrane from the internal opening. In a *horseshoe fistula* the internal opening is usually upon the posterior wall of the bowel, "and from this a tract leads into the ischiorectal fossa, not on one side only, but upon both. Therefore we have one opening into the bowel and one through the skin on either side."[1] In some cases of horse-shoe fistula there is no internal opening; in other cases there are two openings. In an old fistula the track becomes fibrous and cannot collapse. Two or more fistulæ may exist in the same patient. In dealing with a fistula always determine if the condition is stationary or progressive.

The **symptoms** of a complete fistula are the passage of feces and gas through the opening and the flow of a discharge which stains the clothing. In a complete fistula a probe can be carried from the external opening into the bowel. After a time incontinence of feces is apt to come on, repeated attacks of inflammation thickening the rectum and destroying its sensibility. From time to

A B C

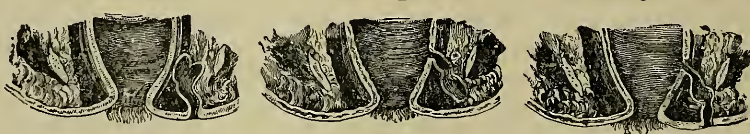

Fig. 780.—Fistula in ano: A, Blind external; B, blind internal; C, complete (Esmarch and Kowalzig).

time the opening will block and new abscesses form. In examining a fistula use Brodie's probe, as its flat handle enables one to locate the direction the bent instrument has taken, and its slender shaft will find its way through a very small channel.

Treatment.—In treating a fistula cleanse the parts, as cleanly work, though it will not prevent pus, will limit suppuration. The external parts are washed with soap and water. The rectum, which must be empty, is irrigated with warm saline solution. Corrosive sublimate should not be used in the rectum because it is irritant, causes a flow of serum, and hence lessens tissue resistance, and is rendered inert as an antiseptic by being converted into sulphid of mercury. Anesthetize the patient with ether unless the fistula is tuberculous, in which case use local anesthesia, spinal anesthesia, or nitrous oxid. Ether is avoided in such cases by many surgeons for fear of the existence of a pulmonary focus. A tuberculous focus in the lung may disseminate after inhalation anesthesia. Place the patient in the lithotomy position. If operating upon a complete fistula the usual method is as follows: Pass a grooved director into the external opening, carry it through the sinus, make it enter the bowel, bring its point out externally, and lift the tissue between the sinus and the surface. If the director ascends above the internal opening, the opening must be made into the bowel from the summit of the sinus. If there is no internal opening, make one. Incise the bridge of tissue which is held up on the director (Fig. 781). Cut

[1] "Diseases of the Rectum, Anus, and Sigmoid Flexure," by Joseph M. Mathews.

the sphincter at a right angle to its fibers, and do not cut it more than once at one operation. If a fistula is non-tuberculous, cut with a knife. If it is tuberculous, divide the tissues with a Paquelin cautery in order to lessen the danger of dissemination of the infection. Push the finger to the depth of the wound, to determine that the sinus does not ascend above the internal opening. Search with a small probe for branching sinuses, and if any are found, slit them open. Examine carefully to see if there is a sinus beneath the mucous membrane of the bowel, and if such a sinus is found, slit it up. Curet all sinuses, and if they are very fibrous, clip away the fibrous wall by scissors. Cut away diseased skin, irrigate the wound with salt solution, pack firmly with iodoform gauze to prevent oozing, and dress with gauze and a T-bandage. The packing is removed in twenty-four hours unless it is soiled earlier, in which case it is promptly removed. After twenty-four hours the wound is irrigated and packed lightly with gauze to its full depth. This dressing should be repeated every day and any bridging of the tissues should be broken down by a probe. If the wound becomes sluggish, it is stimulated with nitrate of silver and sodium iodid is given in small doses three times daily.

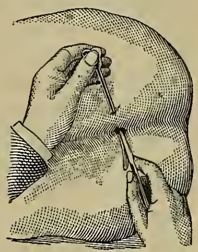

Fig. 781. — Operation for fistula in ano (Esmarch and Kowalzig).

The bowels should be moved after forty-eight hours by enema. The diet should be light and fluid for the first few days after operation, and the bowels should not be restrained by drugs. Get a tuberculous patient out of bed as soon as possible. If there are two fistulæ, cut one through, and when one wound has healed, cut the other. Some straight sinuses can be extirpated and the parts sutured, primary union occasionally resulting.

If a blind external fistula does not heal, every sinus must be incised, and thickened walls must be cut away or scraped away.

In a blind internal fistula an external incision is made to convert the case into a complete fistula, which is then treated as directed above.

In horsehsoe fistula more than one operation may be necessary in order to avoid cutting the sphincter muscle twice in one operation, a proceeding which would probably lead to fecal incontinence. One side alone is operated on at one séance. Sinuses are opened and scraped, the sphincter is divided, the angles and edges of skin are trimmed away, and the wound is packed. When the wound is healed, or nearly healed, the other side should be operated upon.

Any operation will fail if it is not done thoroughly. Operative failure is common after fistula operations. The operation described above usually gives excellent results in simple fistula. It gives reasonably good results even when the internal opening is between the sphincters, although in that case it may leave distinct impairment of fecal control. If the internal opening is in and above the internal sphincter, the operation just outlined leaves as a legacy definite loss of sphincter control and great consequent discomfort (Mackenzie, "Treatment of Fistula in Ano"). For such cases, and particularly for horseshoe fistulæ, Mackenzie (Ibid.) does an operation which does not mutilate the sphincter. He dilates the sphincter; finds and dilates the internal orifice of the fistula; lifts the mucous membrane around it; pares it in the direction of the long axis of the bowel; trims the muscle in the direction of the circumference of the sphincter; sutures the muscle with catgut, the stitches passing at right angles to the fibers; sutures the mucous membrane with chromic gut; makes a flap on the side involved, the flap including the fistulous tract and all of its branches (in a horseshoe fistula he makes a flap on each side); removes all scar from the rectal wall and enfolds the wall by catgut over the stitches within; removes all

of the fistulous tracts from the flap, sutures the fat with buried sutures of catgut, inserts a small drain, and closes the skin.

If fecal incontinence results from an operation for fistula, remove the scar tissue and endeavor to suture the separated muscular fibers. A. W. Mayo Robson ("The Practitioner," Feb., 1903) performs the following operation for incontinence: A crescentic incision, from $\frac{1}{2}$ to $\frac{3}{4}$ inch in depth and taking in about one-half of the circumference of the bowel, is made at the anterior border of the anus. The middle borders of the incision are then pulled apart until the ends of the cut approximate in the middle line, when they are stitched with deep catgut sutures and the skin is sewed with silkworm gut, the immediate result being an incision apparently radiating from the anus. Should an operation be undertaken for fistula if phthisis exists? Many of the old masters said *no*. Mathews sums up the modern view: In incipient phthisis operate; in rapidly progressive fistula operate whether cough exists or not; if much cough exists do not operate unless the fistula is rapidly progressive; in the last stages of phthisis do not operate.

Pruritus of the anus is a symptom and not a disease. It may be due to piles, fissure, seat-worms, eczema, nerve disturbance, kidney disease, gout, jaundice, constipation, inebriety, the opium-habit, torpid liver, dyspepsia, alcohol, tea-drinking, vesical calculus, tobacco-smoking, urethral stricture, uterine disease, diabetes, ovarian trouble, and mental disorder. In some cases it seems to be a pure neurosis and no special causative factor can be recognized. It is vastly more frequent in males than in females, and is especially common in fat men who sweat profusely. It is seldom seen before the age of thirty, except in children suffering from thread-worms. The itching comes on gradually and usually intermittently, but grows progressively worse and worse until it becomes torturing. In many cases it is at first noticed only when warm in bed; in other cases it exists day and night. A violent exacerbation may be excited by worry, anxiety, overwork, dietary indiscretion, a sudden change of temperature, and many other things. The itching finally becomes an unbearable agony, sleep, except in snatches, is impossible, the appetite disappears, the strength fails, and the sufferer may become a nervous wreck. In some cases of pruritus the anal folds are edematous, there are abrasions here and there from scratching, the area is white and moist and gives origin to a fine secretion; in other cases the mucous membrane is dry and fissured.

Treatment.—In every case first of all make a careful examination to find a probable or a possible cause, local, reflex, or constitutional, and endeavor to remove this supposed cause. Then undertake treatment for the pruritus. It is very important to prevent constipation. Kelsey directs that the parts be cleansed twice a day, and after each cleansing the following ointment be applied: Menthol, 1 dr.; cerat. simp., 2 oz.; oil of sweet almonds, 1 fl.oz.; acid. carbolic., 1 dr.; pulvis zinc. oxid., 2 oz. Mathews commends the following mixture: Chloral, 1 dr.; gum-camphor, $\frac{1}{2}$ dr.; glycerin and water, each, 1 oz.[1] In this disease a "scarf skin" forms, which must be made to peel off by the application of iodin, pure carbolic acid, corrosive sublimate (4 gr. to 1 oz. of cosmolin), or calomel (2 dr. to 1 oz. of cosmolin). In obstinate cases paint the parts, night and morning, with a mixture of 60 gr. of alum, 30 gr. of calomel, and 300 gr. of glycerin; or smear with an ointment compossed of $\frac{1}{2}$ part of oleate of cocain, 3 parts of lanolin, 2 parts of vaselin, and 2 parts of olive oil (Morain). In very severe cases, in which the skin is dry and cracked, apply a 5 per cent. solution of eucain to the abraded portions and paint the entire surface with a concentrated solution of silver nitrate. It may be necessary to repeat this treatment several times at inter-

[1] "Diseases of the Rectum."

vals of four or five days. Adler advised us to apply to the parts the day after the silver has been used unguentum hydrargyri nitratis in full strength, only discontinuing on the day a fresh application of silver is made, and the next day resuming the applications of ointment. If during treatment the skin becomes sore, use calomel ointment until soreness disappears. Violent attacks of itching are met by applying hot water and black wash or calomel ointment. This plan of treatment must be pursued for some months (Lewis H. Adler, Jr., "New York and Phila. Med. Jour.," July 29, 1905). I have used this plan with some satisfaction. In severe and protracted cases we may employ the *x*-rays twice a week (J. R. Pennington). I have seen their application productive of great benefit. In some cases we employ the Paquelin cautery, in others we resect the mucous membrane, as in Whitehead's operation for hemorrhoids. Ball divides the sensory nerves going to the implicated skin and has obtained excellent results.

Fissure of the anus is an irritable ulcer at the anal orifice producing spasm of the sphincter. Pain exists because twigs of nerves are exposed upon the floor of the ulcer. Fissure is caused by constipation or traumatism. It is usually posterior.

The **symptom** is violent, burning pain, sometimes beginning during defecation, but usually at the end of the act, and lasting for some hours. Constipation exists, and often pruritus. Examination discloses a fissure, usually at the posterior margin, running up the bowel $\frac{1}{4}$ to $\frac{1}{2}$ inch. Piles often exist with fissure.

Treatment.—The *palliative treatment* is to prevent constipation, to wash out the rectum with cold water, and apply an ointment made by evaporating 2 oz. of the juice of conium down to 2 dr., and adding it to 1 oz. of lanolin and 12 gr. of persulphate of iron. Pure ichthyol frequently promotes healing unless the edges are thick or the base indurated, when operation must be done. Many cases are so sensitive and painful to the touch that medication and examination are almost impossible. These may be made bearable by insufflations of orthoform.

Operative Treatment.—Anesthetize the patient. Thoroughly cleanse the parts. Some surgeons advocate operation without stretching the sphincter. It has always been my custom to stretch the sphincter for fissure. Stretching gives us room in which to work, and by thus paralyzing the muscular fibers the raw surface is put at rest and paroxysms of pain cease to occur. In order to stretch the sphincter the patient is anesthetized, the surgeon's thumbs are inserted into the rectum, and the parts are stretched slowly until the thumbs touch the ischia. After stretching the sphincter the fissure is incised through its base $\frac{1}{4}$ inch deeper than the deepest part of the ulcer, extending $\frac{1}{4}$ inch above and below the diseased tissues, so that the healthy muscular fibers at either end are divided. In cases in which the ulcer is at either the anterior or posterior commissure a V-shaped incision is made, the apex of which should begin $\frac{1}{4}$ inch above the highest point of the ulcer and the diverging line running close to the sides of the fissure, but in healthy tissue.

A search is made by a probe to be sure no pockets exist. Any pocket must be opened and scraped. The floor should be curetted and touched with the solid stick of nitrate of silver. If there are redundant edges, exuberant granulations, a sentinel pile, or a polypus, they should be curetted or excised. The wound is then packed lightly with gauze and the patient kept in bed for twenty-four hours.

Hemorrhoids, or Piles.—There are three varieties of varicose tumors of the rectum, namely: *external*, which take origin without the external sphincter; *internal*, which take origin within the external sphincter; and *mixed* hemorrhoids, which are a combination of the two.

External hemorrhoids are covered with skin. Internal hemorrhoids are covered with mucous membrane. The term "external hemorrhoids" is not strictly accurate, as hemorrhage does not occur in external piles, and all external piles are not related to the external hemorrhoidal veins. An external pile may involve the veins or the skin.

External hemorrhoids are classified as thrombotic, varicose, inflammatory, and connective-tissue external hemorrhoids (Tuttle).

Thrombotic External Hemorrhoids.—These are external hemorrhoidal veins filled with clot. When an external hemorrhoidal vein inflames the parts become itchy, painful, and swollen, and defecation increases the pain. The blood clots in the inflamed vein and sometimes the vessel ruptures.

Symptoms and Treatment.—External piles of this variety are usually, but not always, multiple. Small oval tumors appear beneath the skin or the junction of the skin and mucous membrane. They appear suddenly. The parts itch and pain, defecation increases the pain, and each pile increases rapidly in size. When the vein ruptures, a livid, soft enlargement rapidly forms. External piles of this variety may be absorbed, may become organized into a scar, or may suppurate. These piles do not bleed. In treating external hemorrhoids some surgeons merely use remedies to combat the inflammation. An old plan of treatment is to incise the blood-tumor, turn out the clot, and pack with a bit of iodoform gauze. Mathews freezes the part or injects cocain, catches up the blood-tumor with a volsellum, excises the tumor and the tabs of inflamed skin, dusts the part with iodoform, and dresses it with antiseptic gauze. The bowels should not be allowed to move for two days. Never inject external piles with carbolic acid; it causes great inflammation, violent pain, sloughing, and is not free from danger. If the patient declines operation, order rest, a non-stimulating diet, avoidance of tobacco (Mathews), the use of saline purgatives, injections into the rectum of cold water several times a day, sponging of the anus frequently with hot water, and the application of hot poultices. As the acute symptoms begin to disappear use extract of hamamelis locally; when they have nearly subsided, apply zinc ointment.

Varicose External Hemorrhoids.—They are varicose external hemorrhoidal veins and are visible at the anal margin when the patient strains. They rarely produce pain or discomfort, and it is seldom that operation is necessary. The bowels should be moved daily, but not with violent purgatives, and after each movement cold should be applied to the anus, while the patient is recumbent. Tuttle advocates the use at night of an ointment containing 2 dr. of suprarenal extract and 6 dr. of lanolin; this is spread on cotton-wool, which is applied to the anus and held in place by a T-bandage.

Inflammatory Piles.—By this term we mean edematous inflammation of the anal folds. The inflammation may be due to a traumatism, the presence of an ulcer or fissure, etc. There are burning, itching, and swelling of the anus, which are all greatly increased by defecation. One or more pear-shaped swellings can be seen at the anal margin.

In some cases medical treatment produces cure. This treatment consists, during the first twenty-four hours, in the use of cold and of rest in bed. After this period heat should be employed. Tuttle applies gauze soaked in a 25 per cent. solution of boroglycerid and places a hot-water bag over this. He also recommends the following ointment, to be applied two or three times a day:

℞. Morphinæ sulph. . . . . gr. v–x;
Ichthyol . . . . ʒiv;
Ung. belladonnæ }
Ung. stramonii } . . . . āā ʒj.
Sig.—Apply two or three times a day.

If these means fail, ether is given, the sphincter is stretched, and the tumors are cut away.

Connective-tissue External Hemorrhoids (Skin Tabs).—They are due to hypertrophy of mucocutaneous tissue at the anal margin. Usually they result from acute inflammatory external piles; sometimes they arise gradually as a result of chronic anal or rectal inflammation or irritation, and they may be due to varicose or thrombotic external piles (Tuttle). They produce no trouble when not inflamed. If they cause serious annoyance the treatment is extirpation.

Internal hemorrhoids are varicose tumors of the internal hemorrhoidal plexus, and are found internal to the external sphincter, just within the anus, and they prolapse easily. They are not simply varicosities, but new tissue has been formed, and they are, in reality, vascular tumors. They are covered with mucous membrane. *Capillary* piles are small, sessile, with a surface like a mulberry, and bleed freely. Children are not very liable to develop piles, excepting the capillary form. *Venous* piles are the most common variety. They extend from just above the anal margin of the rectum for an inch or more. They are purple in color, soft, irregular in outline, and are usually multiple. They bleed when irritated by hard fecal masses, but not so easily as the capillary piles. Each pile is composed of a varicose vein, some fibrous tissue, and a few arterial twigs. *Arterial* piles are very unusual. They are large, smooth, pedunculated, bleed easily and freely, and contain, besides a distended vein, arteries of some size.

Anything producing venous congestion in the rectum—constipation, diseases of the rectum, enlargement of the prostate, pregnancy, tumors of the womb, congestion of the liver, cirrhosis of the liver, certain diseases of the heart and lungs, sedentary occupations, relaxing climate, and stricture of the urethra —may cause hemorrhoids.

Symptoms and Treatment.—If there is neither bleeding nor protrusion the piles give no trouble. The first symptom is usually hemorrhage, and rectal examination by the speculum will make clear the condition. After a time, during defecation, the piles protrude; they may reduce themselves when the patient stands up, or it may be necessary to push them in. Pain does not exist in uncomplicated cases, and pain during or after protrusion means "abrasion, fissure, or ulceration" (Mathews).

Palliative Treatment.—This will not cure, but it will give great comfort. Some people only suffer at rare times when the liver is congested, and such subjects will not submit to operation. Remove, if possible, the cause (alcohol, irritating foods, want of exercise, etc.); restrict the diet; insist on regular exercise; give a course of Carlsbad salt, and follow this by the administration of bichlorid of mercury ($\frac{1}{24}$ gr. after each meal). Prevent constipation by a nightly dose of extract of cascara. After each bowel movement wash the parts with a soft sponge soaked in cold water, and syringe out the rectum with cold water and dry outwardly with a soft rag. If the hemorrhoids prolapse after restoring them and injecting cold water, insert a suppository containing 10 gr. of the extract of hamamelis and use another suppository at bedtime. A useful suppository for prolapse is that employed by Tuttle: it contains 5 gr. of ichthyol, 5 gr. of tannic acid, $\frac{1}{3}$ gr. of ext. of stramonium, $\frac{1}{3}$ gr. of ext. of belladonna, and 10 gr. of ext. of hamamelis. Bleeding may be arrested by suppositories, each containing 5 gr. of suprarenal extract. When the piles prolapse and inflame, rub Allingham's ointment on the parts (2 dr. each of ext. of conium and ext. of hyoscyamus, 1 dr. of ext. of belladonna, and 1 oz. of cosmolin). Mathews uses 12 gr. of cocain, 1 dr. of iodoform, $\frac{1}{2}$ dr. of ext. of opium, and 1 oz. of cosmolin. Grant uses an ointment containing 8 gr. of morphin, 12 gr. of calomel, and 1 oz. of vaselin. This is applied after bathing

the part with hot water. If the piles are protruding and reduction cannot be effected, put the patient to bed, give a hypodermatic injection of morphin, and apply hot poultices. If reduction cannot soon be effected, divulsion of the sphincter must be practised or radical operation must be resorted to.

Operative Treatment.—Give a saline the morning before and an enema the evening before the operation, and wash out the rectum well the morning of the operation. In treating by *injection of carbolic acid* the sphincter should be divulsed while the patient is under the influence of nitrous oxid gas unless the pile is thrombotic. "Under gas muscular relaxation does not obtain as in the use of ether. Hence dilatation under gas can be more rapidly induced, as we have the sphincteric rigidity as a guide in knowing exactly how much force may be employed in the individual case" (Lewis H. Adler, Jr., in "Jour. Am. Med. Assoc.," Jan. 21, 1905). The surgeon must be careful not to tear the parts. The tumors are drawn out or, if gas was not given, the patient strains them out. An injection is given by a hypodermatic syringe into the center of the pile, and as each pile is injected it is pushed into the rectum. Only one or two piles are injected at each séance, and the operation is not repeated for one week (Geo. W. Gay, in "Boston Med. and Surg. Jour.," Dec. 5, 1901). The dose for each pile is 1 or 2 min. of a 10 per cent. solution of carbolic acid. The injections relieve the condition, but are rarely absolutely curative and are not without

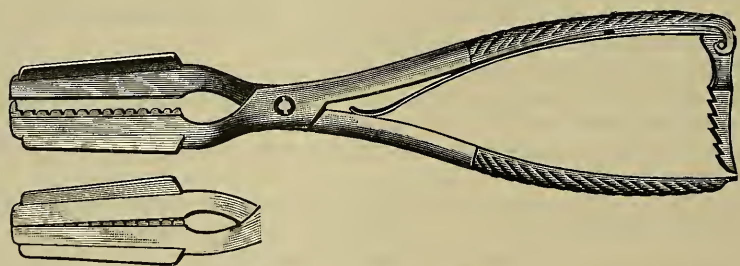

Fig. 782.—Brick's pile clamp.

danger, and may produce abscess, sloughing, hemorrhage, phlebitis, pyemia, stricture, and even death (W. T. Bull-Kelsey). Dr. Collier F. Martin ("American Medicine," August 27, 1904) maintains that the method is safe and satisfactory. He injects equal parts of a French preparation of phenol and distilled water, freshly mixed and filtered. From 7 to 15 min. are injected into a pile and only one pile is injected at a séance. In from five days to one week another injection may be given. Before beginning a course of injections the sphincter is stretched while the patient is under nitrous oxid and oxygen. It is not necessary to repeat this for future injections. During injection a special speculum is used. The pile protrudes into the speculum, is cleansed with a 1 per cent. solution of creolin, and the injection is thrown into the most prominent part of the pile. The speculum is withdrawn before pulling out the needle. This maneuver prevents escape of injection and arrests bleeding. I seldom employ the injection treatment. I never use it if the patient consents to the clamp and cautery operation or to ligation. The *clamp and cautery* is, in the great majority of cases, the operation of choice. It requires but a few minutes to do it; after it is done there is little or no postoperative pain, in very many cases retention of urine does not occur, and the patient usually is about again within ten days. The patient is anesthetized and the sphincter is carefully and thoroughly stretched. The stretching of the sphincter is very important. It gives free access to the parts, prevents subsequent spasm and pain, and lessens the likelihood of venous bleeding after operation. The

pile is caught by forceps and drawn outside of the sphincter. Many use Smith's clamp. It is applied with the ivory surface against the mucous membrane of the bowel. I use the clamp devised by Dr. J. Coles Brick (Fig. 782). From the bite of Brick's clamp the pile cannot slip, as the blades come evenly and firmly together. The pile is cut off and the stump is seared with the Paquelin cautery at a dull-red heat. Pile after pile may be thus treated, care being taken to leave some mucous membrane at each side of every pile. If this precaution is not taken, healing will be slow and stricture will result. After cauterization is complete a speculum is inserted and the blades are widely opened. Any bleeding-points are at once ligated. This is a most important precaution. Packing is never inserted. I formerly used it, but have given it up. It is of no service and produces severe pain and edema. The treatment from this point is identical with that advised below after the use of the ligature. *Excision* is preferred by Allingham. He stretches the sphincter, holds it open with a retractor, catches up the pile, cuts it off, and twists the bleeding vessels. Some prefer to pass a silk or catgut suture, cut off the tumor, and tie the thread (Fig. 783). *Whitehead's operation* (Fig. 784) is only to be performed in severe cases, when the piles are extremely large and form a protruding circular mass. Primary union is rarely secured. When first introduced the operation was viewed with favor, but experience shows it is sometimes followed by disastrous consequences.[1] Stricture not infrequently arises after its performance; fecal incontinence occasionally results, and anal anesthesia with inability to restrain the passage of gas is common. After this operation the anus is permanently more or less moist. The entire pile-bearing area of mucous membrane is dissected out and the cut margin of mucous membrane is pulled down and stitched to the surface. The sphincter may be dilated as a preliminary measure.

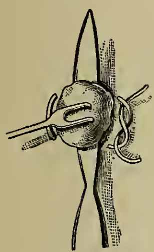

Fig. 783. — Extirpation of hemorrhoids (Esmarch and Kowalzig).

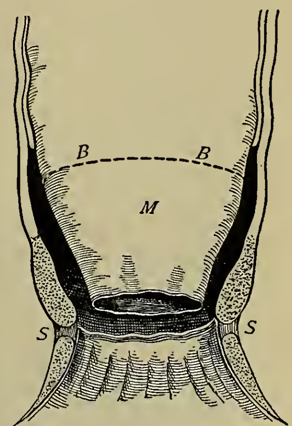

Fig. 784.—*S*, *S*, The lower circular incision along Hilton's white line; *M*, tube of mucous membrane dissected from the sphincter; *B*, *B*, dotted line showing the place for the upper circular incision (Edmund Andrews).

The *application of the ligature* is an easy and useful method. It is not so rapid as the cautery, is followed by more pain, healing requires a longer time, and stricture is more common. In this operation, after anesthetizing, stretch the sphincter and treat each hemorrhoid separately. Catch a pile with a pair of forceps or a volsellum, pull it down, and cut a gutter through the skin-margin if the pile is of the mixed variety; tie the small piles without transfixing, but transfix the large piles; tie with silk (coarse silk for the large piles, finer silk for the small piles); cut off each tumor beyond the thread and cut the ligatures short. Treat the other piles in the same manner. Irrigate with hot normal salt solution. Do not insert packing. Place a 2-gr. opium suppository in the rectum. Apply a gauze pad and a T-bandage over the anus. The opium locks up the bowels. The patient is kept on a light diet for three days, at the end of which time a saline may be given. Just before the bowels act remove the dressings and give an enema of warm water or of

[1] Andrews, in "Mathew's Medical Quarterly," Oct., 1895.

glycerin. After the movement wash the parts first with dilute peroxid of hydrogen and next with hot salt solution, dust with iodoform, and apply a gauze pad over the anus. Irrigate daily until healing is complete. After the tenth day examine with a speculum to see that the ligatures have come away; if any are found in place, remove them.

Prolapse of the Rectum.—If the mucous membrane is prolapsed the condition is commonly called *prolapsus ani;* if the entire thickness of the rectal wall is prolapsed, it is commonly called *prolapsus recti* (Fig. 785). The term "prolapse of the anus" is an incorrect and objectionable one, and we should designate such cases *prolapse of the rectal mucous membrane, incomplete* or *partial prolapse.* If all the coats of the bowel descend the condition should be called *complete prolapse* or *procidentia.*

Incomplete Prolapse (Partial Prolapse).—In this condition the mucous membrane of the rectum protrudes from the anus. In normal conditions the

Fig. 785.—Rectal prolapse.

membrane protrudes during defecation and at once retracts when the act of defecation terminates. In the condition under discussion the mucous membrane remains protruded because the submucous tissues being stretched and relaxed find it difficult or are unable to draw the mucous membrane in again. In this condition a ring of mucous membrane or only a portion of its circumference may protrude. It is particularly common in early youth and in old age. Prolapse is apt to occur from excessive straining at stool and is commonest in feeble, ill-nourished children. A polypus may be the cause. Piles and worms may lead to prolapse. Straining from phimosis, stone in the bladder, or urethral stricture may be causative. Its development is favored by the use of articles of food which cause frequent movements of the bowels. If an individual sits a long time on the seat of the closet or on the chamber the development of prolapse is favored. The condition comes on gradually and is at first painless. For some time it reduces itself spontaneously after defecation, but reduction becomes more and more difficult. A common custom of sufferers is to push it

by the fingers above the grasp of the sphincter. Sometimes, but seldom, it becomes strangulated. A recent prolapse is pink, an older one is angry red, one which is tightly caught is purple, a strangulated one is deep purple and soon becomes black from gangrene. If the prolapse is of the entire circumference it shows radial folds of mucous membrane. It frequently bleeds. Prolapse, be it large or small, tends to recur again and again, and eventually the mucous membrane inflames, ulcerates, or sloughs. Prolapse of all the coats may ensue (see below). The condition is sometimes confused with hemorrhoids, but in prolapse the protruding mass is circular and has a depression in the center, whereas hemorrhoids are distinct masses. Further, hemorrhoids are very rare in children. Hemorrhoids often exist with prolapse of the mucous membrane and frequently cause it. In prolapse of the mucous membrane there is no sulcus between the sphincter muscle and the anterior portion of the protrusion, in complete prolapse there is.

Treatment.—*Palliative* treatment forbids straining at stool and amends an improper diet. Phimosis must be corrected; stone in the bladder must be crushed or cut for and removed; stricture must be dilated; hemorrhoids and polypi are to be removed. Give an enema of cold water just before going to stool in order to hurry the emptying of the rectum. If prolapse occurs, the protrusion must be bathed with cold water and restored. Constipation must be prevented (enemata of water or glycerin may be used), and after each movement several ounces of an infusion of white oak bark (1 ounce of quercus to a pint of water) should be injected. If a prolapse is caught firmly, paint it with cocain and adrenalin, place the patient in the knee-chest position, apply hot compresses, grease it with cosmolin, insert a finger into the rectum, and apply taxis around the finger (Mathews). If this fails, cover a finger with a handkerchief and insert the wrapped digit into the rectum; if this proves futile, invert the patient before manipulation. Do not give a general anesthetic unless it is imperatively necessary; the vomiting so often caused by ether and chloroform might reproduce the prolapse. After reduction apply a compress upon the anus, direct that it be worn when at stool, and before each act of defecation give an injection of cold water containing an astringent (tannin or fluidextract of hydrastis). Most cases in children can be cured without operation. Some cases in adults and obstinate cases in children may be treated by painting the prolapse with fuming nitric acid, greasing it with olive oil, and restoring it. Some cases require excision of the mucous membrane, the divided edge of this membrane being stitched to the skin. In other cases the protrusion is stroked longitudinally with the actual cautery and restored. When the surgeon comes to operate for recurring prolapse, it will often be found to have modestly withdrawn and he may be obliged to stretch the sphincter to bring it into view.

Complete Prolapse (Procidentia).—In this condition all of the rectal coats protrude. There are said to be three degrees of this condition. In the first degree the prolapse begins at the anal margin and its outer surface is continuous with the peri-anal skin, there being no sulcus between. It is usually a consequence of prolapse of the mucous membrane. In the second degree (genuine procidentia) the prolapse begins on a level or above the level of the lower margin of the peritoneum and projects out of the anus. In the third degree the prolapse begins at the origin of the rectum or in the sigmoid, and is, in reality, a protruding intussusception. Some cases come on suddenly. The prolapse of the first degree has no furrow between it and the perianal skin, and the folds are circular instead of longitudinal. It is usually treated as is prolapse of the mucous membrane. If simple methods fail, it will be necessary to do an operation to lessen the size of the anal orifice. In prolapse of the third degree the treatment is as for intussusception. It is prolapse of the second degree we

consider here. It is more common in adults than in children. There are many theories as to its causation. Esmarch regards it as due to inflammation of the rectum, which spreads to all the coats and also to the perirectal structures. Another theory (Jeannel's) is that the small intestine is in a state of ptosis, and by falling into Douglas's culdesac presses upon and causes atrophy of the levator ani muscle. The most probable theory is that the condition is, in reality, hernia (Waldeyer, Zuckerkandl, Moschchowitz). Moschchowitz ("Surg., Gynec., and Obstet.," July, 1912) makes a powerful argument to prove that the intestine in Douglas's culdesac causes a bulge of the anterior rectal wall, that this bulging part of the wall grows larger and descends, and that finally the entire circumference of the rectum is dragged down.

Complete prolapse is usually preceded by chronic constipation, great straining being necessary to effect defecation. Chronic rectal catarrh is also a common antecedent.

A mass sticks out of the rectum and there is a purulent discharge which often contains blood. The protruding mass (which is seldom over 6 inches in length) is covered externally with mucous membrane (which may be normal, inflamed, ulcerated, or bleeding) and is lined by normal mucous membrane (Moschchowitz, Ibid.). The opening is at the apex of a canal directed backward. The anterior part of the protrusion is greatly larger than the posterior part, the anterior part is usually tympanitic, and the posterior part dull on percussion (Moschchowitz, Ibid.). There is a deep furrow between the anterior portion of the sulcus and the anal margin. The furrow, as a rule, is about 1 inch deep.

Early in the case the prolapse is reduced spontaneously, later it must be reduced by the hand. It may become incarcerated or strangulated. The protrusion when strangulated becomes gangrenous.

Treatment.—In children the condition may often be cured by the methods used for prolapse of the mucous membrane. If a prolapse is caught tightly, apply hot compresses to reduce swelling, paint it with cocain and adrenalin, put the patient in the knee-chest position, and reduce as described under partial prolapse. General anesthesia is undesirable because of the probability of vomiting with consequent straining. After reduction apply a support. Electricity is used by some, injections of astringents under the mucous membrane by others. Operation is necessary for prolapse in most adults and in some children. As a preliminary, hemorrhoids, ulcerations, etc., must be cured. A multitude of operations have been recommended. Some try to constrict the anal opening (cauterization by the actual cautery, nitric acid or chlorid of zinc, removing a wedge-shaped piece from posterior rectal wall followed by suturing, twisting the rectum, injections of paraffin about the sphincter, and various other plans). Such operations are entirely inefficient. Some operate on the bowel higher up, striving to increase support. Moschchowitz also mentions "methods which pay particular attention to the fixation apparatus of the rectum." One plan is to operate through an abdominal incision, fixing the sigmoid to the abdominal wall—an unphilosophical operation "because the distal end of the sigmoid is fixed to the sacrum, and pulling can have very little, if any, effect upon the prolapse of the rectum" (Moschchowitz, Ibid.).

I have abandoned the operation of stitching the sigmoid to the abdominal wall (*colopexy*) because it is dangerous to thus anchor the gut and because, I believe, it always fails to cure. Mikulicz's operation of excision of the prolapse has elements of decided danger, but may cure the case. I apparently cured 1 case this way, but in another case the condition recurred.

Moschchowitz's operation is the most reasonable one. The abdomen is opened, the rectum is held taut, and the culdesac of Douglas is obliterated by silk or linen sutures. The pelvic fascia is included in the sutures.

Ulcers of the rectum are divided into the simple traumatic, the syphilitic, the tuberculous, the dysenteric, the gonorrheal, and the malignant. *Simple* ulceration is due to abrasion with fecal masses or a foreign body, the abraded area ulcerating. It may follow an operation for piles and also protracted labor ("Diseases of the Rectum," by Allingham), and is apt to be single. The base and edges of a simple ulcer are neither prominent nor hard and stricture rarely forms. *Syphilitic* ulceration is a tertiary lesion commonest in women. There are numerous small ulcers of the mucous coat or submucous tissue, but little indurated, with sharp-cut edges which are not undermined. These ulcers fuse and constitute one large irregular ulcer; fibrous tissue forms in the wall of the bowel, induration becomes noticeable, and stricture follows. There is profuse discharge and fistulæ are apt to form. Such ulcers may be surrounded by nodules of a bluish color. In many cases the first condition is stricture due to the formation of masses of fibrous tissue in the rectal walls, and ulceration occurs secondarily. In syphilis there may be a breaking down of a huge gummy mass or of multiple gummata. It has been proved by the microscope that tuberculous ulceration may arise in the rectum. *Tuberculous* ulceration presents a conical ulcer with overhanging edges and a pale-red base. There is some mucous discharge, some tenesmus, and a little pain. Tuberculosis is seldom *directly* responsible for stricture (see page 1186). Dysentery, catarrh, diabetes, Bright's disease, neoplasms, and foreign bodies may produce ulceration of the rectum.

Symptoms.—There may be merely uneasiness about the rectum, but sometimes there is severe burning pain on defecation, and perhaps for some time after the act. There may be constipation or diarrhea, the patient strains at stool, and the stools may contain blood, mucus, or pus. As a rule, there is diarrhea on rising in the morning, the first movement consisting of blood and mucus, and the next movement being fecal. The history should be carefully inquired into; tuberculosis should be sought for; the question of syphilis should be investigated. A digital examination enables the surgeon to feel the ulcer, and an examination by means of an ordinary speculum or an electric proctoscope brings it into view.

Treatment.—In *simple* ulcer empty the bowel by the administration of a saline cathartic, wash out the rectum with hot water after the saline has acted, introduce a speculum, touch the ulcer with pure carbolic acid or silver nitrate (40 gr. to 1 oz.), place the patient in bed, restrict him to a liquid diet, and every day inject iodoform and olive oil (10 per cent.) or insufflate iodoform into the rectum. If this fails, give ether, stretch the sphincter, incise the ulcer through its entire thickness, and cauterize with fuming nitric acid, caring for the case subsequently as we would a patient who had had piles ligated. In *tuberculous* ulcer improve the general health, send the patient to a genial climate, or at least into the sunlight and fresh air, prevent constipation, give nutritious food, especially fats, wash out the rectum every day with hot water, and insufflate iodoform or inject iodoform emulsion. Touch the ulcer once a week with silver nitrate (10 gr. to 1 oz.). In *syphilitic* ulcer give antisyphilitic treatment and treat the ulcer locally, as is done in tuberculous ulcer. *Dysenteric* ulcer requires injections of hot water, the touching of the ulcer with pure carbolic acid, insufflations of iodoform, and special treatment of the dysentery.

Benign Tumors of the Rectum and Anus.—These tumors may be of the connective, epithelial, or muscular tissue type. Of the first there are fibroma, enchondroma, lymphadenoma, lipoma, and myxoma; of the second, adenoma and papilloma; of the third, myoma and fibromyoma. Many benign tumors appear in polypoid form. A polyp is a tumor with a pedicle. A polyp may be a fibroma, myxoma, myoma, papilloma, or adenoma. Papilloma is a rare growth, usually has a broad pedicle, but may have no pedicle.

It does not occur in childhood. A papilloma bleeds profusely and causes a discharge of mucus. A polyp causes no pain unless ulceration occurs. It causes bleeding and mucous discharge. On coming from stool the patient feels as though the rectum still contains feces. A polyp may protrude during defecation. It can be detected by digital examination and can be readily seen through a proctoscope. There may be one polyp; two, several, or many polypi. Polypi are most common in children. (See Adler, in "Annals of Surgery," Dec., 1909.) The most common forms of tumor are the myxoma, hypertrophied solitary follicles, adenoma, fibroma, and lipoma. Myxoma is most common in children. Fibroma originates in the connective tissue or the submucosa and is very rare. It may arise at the upper end of a fissure. It has a long pedicle and may become very large.

Symptoms of tumor are dull, aching pain, tenesmus, frequent defecation, and sometimes ulceration of the mucous membrane. In a non-polypoid benign tumor there is absence of hemorrhages and of mucous discharges.

Treatment.—Remove the tumor after dilating the sphincter. In tying or snaring off polypi it should be borne in mind that the peritoneum may be invaginated in the pedicle and, therefore, no traction on it should be made when operating. Sessile growths are dissected out. The postoperative treatment is practically the same as for hemorrhoids.

Cryptitis (*Inflammation of the Crypts of Morgagni*).—These crypts, five to ten in number, are situated in the mucous membrane of the rectum, about 3 cm. from the anus. They occasionally become packed with mucus or feces. There is quite severe pain referred to the site, especially after defecation. In this condition the examination of the anus by the finger is extremely painful. The inflamed crypts may be detected by examination through the speculum.

Treatment.—Divide the affected crypts, curet away any granulations, and allow the parts to heal.

Non-cancerous stricture of the rectum may be congenital or acquired. There are two forms of acquired stricture: first, stricture due to external pressure; second, stricture due to primary narrowing of the rectal lumen.[1] Stricture due to external pressure is very rarely complete, and may be caused by bands of adhesions or a tumor growth. The second form may be produced by syphilitic tissue, ordinary inflammatory tissue, cicatrices after operations, sloughing, tuberculous, syphilitic or dysenteric ulceration, rectal gonorrhea, and traumatism. The usual seat of simple stricture is from 1 inch to $1\frac{1}{2}$ inches above the anus. The deposit may be limited to the submucous coat or all the coats may be involved. It is very seldom that stricture arises as a result of abrasion from fecal masses or foreign bodies. It may follow an operation for piles if considerable tissue is removed, and is an occasional sequence of Whitehead's operation. Stricture due to dysentery is extremely rare, and no case has ever been reported to the United States Pension Office (Peterson). The existence of stricture as a result of rectal gonorrhea has not been positively proved. A majority of sufferers from rectal stricture have labored under syphilis, but it is not probable that the lesion is syphilitic in all or even in most of them. The stricture may be due to the formation of fibrous tissue and ulceration may or may not occur. It may be caused by the contraction and healing of a large ulcer. Some maintain that tuberculous stricture does occur. Mathews dissents from this view and points out that the disposition of tuberculous matter is to break down, and before the rectum can be strictured from tuberculosis it breaks down from ulceration. Peterson[2] says a large proportion of the victims of rectal stricture die of phthisis, and that one-third of so-called syphilitic cases are tuberculous. It may begin as an ulcer or as an infiltration of submucous tissue. Although a syphilitic or a tuberculous

[1] Reuben Peterson, in "Jour. Am. Med. Assoc.," Feb. 3, 1900. [2] Ibid.

lesion may cause rectal stricture, in most cases such lesions simply expose the tissues to infection, and benign rectal stenosis results from the infection. Tuberculosis may cause stricture, but does so indirectly rather than directly.

The **symptoms** of rectal stricture are constipation, pain on defecation, straining at stool, perhaps the presence of blood and mucus in the stools, an open anus, and the passage of stools flattened out into ribbons if the stricture is low down. In some cases there is fluid diarrhea, solid fecal matter being retained above the stricture. The stricture is found by the finger or by the soft-rubber bougie, used with the utmost gentleness and care. A stiff instrument or the rough use of any instrument would be dangerous and might rupture the rectum. In syphilitic cases, in tuberculous cases, and in benign cases the fibrous thickening is usually in the submucous coat, and in syphilitic and tuberculous cases the mucous membrane is apt to ulcerate. It is said that complete obstruction may arise. I have seen obstructive symptoms, but never *complete* obstruction in rectal stricture. Distention of the abdomen and colic are very usual.

The **treatment** of non-cancerous and primary narrowing of the rectal canal is rest, non-stimulating diet, warm-water injections, mild laxatives, and hot hip-baths. Cocain suppositories may be needed. Any existing disease is treated. Bougies are passed every other day. Use a soft-rubber bougie, warmed and oiled, and introduce it gently. If only the method of gradual dilatation is employed the patient must for the remainder of his life pass a bougie from time to time. For fibrous strictures forcible dilatation (*divulsion*) by a special instrument is employed or incision is practised. Incision (*proctotomy*) may be either external or internal. In internal proctotomy one or more incisions are made from the rectum through the stricture down to healthy tissue, the first cut being in the middle line posteriorly. External proctotomy, which divides the sphincters, is apt to leave incontinence as a legacy. Electrolysis finds some advocates, but on what grounds it is difficult to see. In some cases the rectum should be removed. In incurable cases perform inguinal colostomy.

Cancer of the rectum is the cancer of the bowel most often met with. According to Abbe ("Keen's Surgery") rectal carcinomata constitute three-fourths of all intestinal tumors. Its growth may be primarily malignant or may arise from an adenoma. The commonest growths are composed of cylindrical cells, and may be either soft or scirrhous. In cases secondary to epithelioma of the anus ordinary epithelioma arises.

In most rectal carcinomata the cells present a tubular arrangement surrounded by a more or less plentiful stroma of connective tissue. In soft tumors the connective tissue is scanty; in hard tumors it is plentiful.

Cancer is most common after the age of forty, but it not unusually occurs before the thirty-fifth year, and is sometimes seen as early as the twenty-fourth year or even earlier. "Of 115 cases of cancer of the rectum at the Rostock Clinic, 4 occurred in patients between fourteen and seventeen years of age" (Miles Porter, in "New York Med. Jour.," Feb. 10, 1912). Extensive ulceration occurs. If a hard ring encircles the rectum the lumen of the tube is greatly and progressively diminished. In cases of diffuse infiltration the lumen is not greatly lessened. In growths involving the anus the inguinal glands are involved and also the glands in the hollow of the sacrum. In growths limited to the rectum proper the glands back of the peritoneum in the sacral hollow are involved, and the inguinal glands are involved late or not at all.

Symptoms.—In the beginning and for a considerable time after there are no symptoms. There may be none for a year or more. Symptoms begin with ulceration or constriction. The symptoms of rectal cancer are like those of non-malignant stricture, except that the pain is usually greater and the hemorrhage more severe. Constipation is apt to alternate with diarrhea. The diarrhea

is usually in the morning. Unfortunately, in many cases symptoms are long trivial; in fact, pain may be absent until the disease is far advanced. Mucopurulent or bloody stools are often thought to result from dysentery or hemorrhoids, which latter condition, however, may be only an accompanying condition of rectal cancer. The above symptoms may, on the patient's say-so, have been accepted by the physician, without any local examination, as caused by hemorrhoids. The patient, again, may have only imagined the presence of hemorrhoids, since, according to his notion, the above symptoms must result from hemorrhoids, with which condition so many of his friends with like complaints are afflicted. Loss of strength, emaciation, and cachexia are generally noticeable only in the late stages of rectal cancer. Only in the very latest stages the characteristic odor is perceptible, the patient becomes septic, and abscesses attended by gangrene may form (Ernest Jonas, in "Interstate Med. Jour.," No. 4, 1906). The finger and the speculum make the diagnosis. In rectal cancer metastasis occurs late. The most favorable cases for operation are those in which the growth is small and movable. Accurately define the extent of the growth, and endeavor to make out if it has invaded the cellular tissue outside of the rectum, the prostate, the bladder, the sacrum, the uterus, etc.

Treatment.—In every case of cancer of the rectum the following questions must be considered: Shall we perform a radical operation in hope of producing cure or at least greatly prolonging life? In what cases should a radical operation be attempted? It is the proper procedure if there are no metastatic deposits, if the patient is in fair general condition and free from serious organic disease, and if the cancerous bowel is movable and not fixed by dissemination to adjacent structures. As W. Watson Cheyne ("Brit. Med. Jour.," June 13, 1903) says, a slight adhesion to the vagina is not a contraindication, because this portion of the vagina can be readily removed with the diseased rectum. Some surgeons will not attempt radical operation if they cannot pass a finger through the growth. I do not regard high position as forbidding operation, although, of course, it makes it more dangerous to life and less promising as to cure. Cheyne is of the same opinion. When the surgeon is first called to a case of cancer of the rectum it is usually found to be so far advanced as to be inoperable. In at least 75 per cent. of my cases radical extirpation was impossible when I first saw the case.

If a radical operation is determined on, the next question to answer is, Shall we, or shall we not, perform *preliminary colostomy?* If the cancer is very low down, involves the anal canal, and is to be removed from the perineum, preliminary colostomy is rejected by many. I believe that even in such cases it should be done. If the cancer is high up and we propose to attack it by Weir's method or the Quenu-Mayo method, preliminary colostomy should not be done. If Kraske's operation is to be performed, I believe preliminary colostomy is usually indicated. It enables us to cleanse the area upon which operation is to be performed, and to keep the wound clean, and gives us a much better chance of obtaining primary union. In cases in which the sphincter is retained and it is possible to anastomose the divided ends of the rectum together, colostomy is not necessary; and if an artificial anus has been made in such a case, another operation will be required to close it. As a matter of fact, I have found it always difficult and usually impossible to suture the divided ends of the gut together after Kraske's operation, and I now follow the advice of Keen, and always precede Kraske's operation by colostomy. The abdominal incision necessary to reach the bowel to do colostomy may be used to permit of exploration, but it is wiser to have a median incision for this purpose. I consider exploration as of the first importance. It enables the surgeon to examine the outer surface of the rectum, to detect glandular involvement, to find out if there has been metastasis to the liver, and to

determine with certainty whether or not the cancer is operable. Several times in cases of small and apparently operable cancer of the rectum I have found on opening the abdomen extensive glandular involvement or unsuspected metastasis to the liver, and once I found another cancer 4 inches above the one to which attention had been directed. It is my custom to make a median incision for exploration and then a small incision through which to bring out the gut for colostomy. A large abdominal incision for colostomy is objectionable. I strongly object to operating at all on rectal cancer without a preliminary exploratory operation. If radical operation is rejected (and about three-fourths of the cases, when first seen by the surgeon, are obviously beyond such aid), palliative treatment is desirable. The best palliative treatment is the operation of inguinal colostomy. If this is refused, what shall be done? One plan is to introduce a tube through the stricture daily, wash out the rectum with warm water, and after washing inject emulsion of iodoform (10 gr. to 1 oz. of sweet oil). Injections of chlorid of zinc (1 gr. to 1 oz. of water) lessen the foulness of the discharge. The bowels are opened regularly by laxatives, and if the growth causes obstructive symptoms it is scraped away with a sharp spoon. Opium is given to relieve pain. The advantage of this plan is that the patient does not suffer from the unpleasantness of an artificial anus. Sooner or later, however, the growth gets outside of the bowel, and terrible pain will arise from involvement of the sacral plexus. W. Watson Cheyne ("Brit. Med. Jour.," June 13, 1903) would restrict palliative treatment of this character to cases in which fungating masses grow from one side of the bowel.

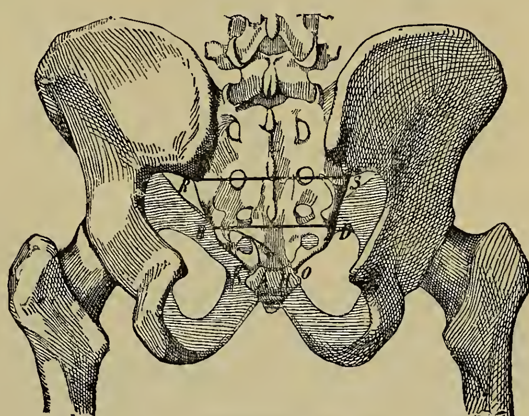

Fig. 786.—Different levels of resection of the sacrum: *K–O*, Kocher's line; *B–O*, Kraske's; *B–H*, Hochenegg's; *B–D*, Bardenheuer's; *R–S*, Rose's (Mass.).

If a growth encircles the bowel and produces symptoms of obstruction, *palliative colostomy* should be performed. This operation gives great comfort to the patient and allays pain by intercepting the feces before they reach the cancer. I am not convinced that it distinctly retards the growth of the cancer or notably prolongs life. Unfortunately, colostomy does not do away with pain if the sacral plexus is involved. I have had no experience with radium in inoperable cancer of the rectum and have never seen the *x*-rays produce any marked or lasting improvement. *Operative treatment* includes one of several procedures. Excision of the rectum from below (*Cripps's operation*) is practised by some if not more than 3 inches require removal, if the peritoneum is not invaded, and if the adjacent organs are free from disease. The peritoneum must not be opened in Cripps's operation. After the growth is removed the divided rectum is pulled down and sutured to the skin. As the sphincter is sacrificed the condition would be dreadful without an artificial anus. A perineal anus without a sphincter is vastly more distressing than an inguinal anus. I seldom do perineal excision (it does not permit any considerable removal of lymph-glands). When of recent years I have done it I have preceded it by exploratory laparotomy and the formation of an inguinal anus. In some cases in women it may be possible to remove a low growth without

damage to the sphincter through an incision in the posterior vaginal wall. Excision of the rectum after excising the coccyx and a portion of the sacrum (*Kraske's operation*, that is, excision of the rectum after sacral resection, Fig. 786, *B–O*) is a procedure which permits removal of the entire tube, portions of the colon, and even of adjacent parts. The peritoneum is opened deliberately in this operation, and is subsequently closed with sutures before the gut is opened. The glands from the mesocolon are always removed. The lower end of the upper segment of bowel is fastened in the wound, or, if colostomy has been previously performed, may be closed. In some few cases in which it is not necessary to remove the lower end of the rectum, the two portions may be anastomosed after resection of a part of the tube. Kraske's operation may be done by an osteoplastic method, the bone not being removed. It is well to precede a Kraske operation two weeks by an inguinal colostomy, which permits of cleansing the lower bowel of feces and lessens the chance of severe wound infection and delayed healing after the removal of the rectum. Preliminary colostomy may make the operation of extirpation more difficult by fixing the intestine, and thus interfering with the necessary drawing down of the gut (E. H. Taylor). If the growth is extensive and the mesocolon short, it may be best to perform right inguinal colostomy, but in most cases left inguinal colostomy is preferred (Gerster). The colostomy remains open during the patient's life, except in those rare cases of Kraske's operation in which the con-

Fig. 788.—Lower end of rectum everted through the anus and the upper end of bowel drawn out of the abdominal cavity (Weir).

tinuity of the rectum can be reëstablished after excision of the growth. In such cases the artificial anus may be closed some time after resection of the rectum.

Robt. F. Weir ("Med. News," July 27, 1901) has been so much impressed with the difficulties and dangers of Kraske's operation in a case of high carcinoma that he now employs it solely in cases in which there is freedom from disease for 2 inches immediately above the anus and in which the cancer does not extend more than 5 inches above the anus. In high cases he does the following operation: Open the abdomen above the pubes, separate the peritoneum so that the bowel and "contents of the sacral curve" are liberated behind nearly "to the tip of the coccyx and in front of the edge of the prostate." The tumor is then tied off with tapes (Fig. 787). The portion of the rectum bearing the tumor is removed, the lower end of the bowel is everted through the anus, and the upper end is drawn out of the abdominal incision (Fig. 788). The upper end is then caught with forceps and drawn through the everted lower end of the rectum (Fig. 789, *a*). The ends of the two everted portions (Fig. 789, *b*) are sewn together, the everted bowel is replaced, the divided peritoneum is sutured to shut off the peritoneal cavity, and posterior drainage is inserted (Fig. 790). In the Quenu-Mayo operation the object is

to remove all of the diseased glands as well as the cancer (Wm. J. Mayo, in "St. Paul Med. Jour.," April, 1906). The patient is placed in an exaggerated Trendelenburg position and the belly is opened by a median incision. The growth is studied to see if it is removable, and a search is made for enlarged glands which might cause us, and for secondary growths which would cause us, to abandon the operation. If we conclude to attack the growth, pack away all the intestine except the sigmoid, catch two clamps across the sigmoid, one of them being on the level of the sacral promontory. Divide the gut between them. Free the mesosigmoid by lateral cuts and bring the proximal stump out of the belly, ligate it, and apply a purse-string suture to invert it. A gridiron incision is then made on the left side and the proximal stump is pulled through it and is sutured there. Incisions are now made in the sides and in front to liberate the rectum, the inferior mesenteric artery is tied above and to the left of the promontory, the fat and glands are thoroughly removed from the sacral hollow, vessels being tied as cut, except the middle sacral and middle hemorrhoidal vessels, which are tied before division. The area is now packed with gauze and the patient is put in the lithotomy position. The rectum is packed with gauze, the anus is sutured, and the rectum is separated from the prostate and urethra or from the vagina from below upward to just above the levator

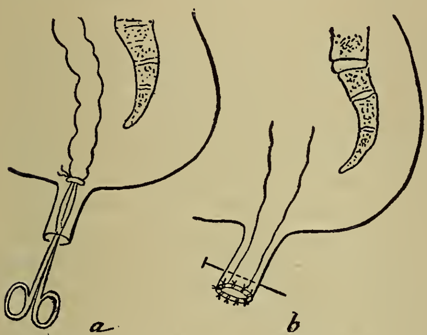

Fig. 789.—*a*, The upper bowel drawn out through the everted lower end of rectum; *b*, the ends of the two portions of the rectum sewn together (Weir).

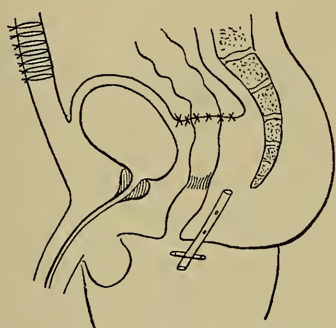

Fig. 790.—The united bowel replaced with posterior drainage and the divided peritoneum so sewn together as to shut off the general peritoneal cavity from the pelvis (Weir).

ani muscle. An assistant presses the cancer-bearing fragment carrying glands down from the abdomen and the surgeon removes it from the perineum. The peritoneum is sutured within the abdomen, room being left for a small drain which protrudes from the perineum. The perineal wound is narrowed by sutures and the wound in the belly is closed. In twenty-four hours the protruding end of the sigmoid is opened and an artificial anus is thus made.

(See Joseph A. Blake's views as to "The Operation of Choice in Carcinoma of the Rectum," "New York Med. Jour.," July 1, 1911.)

The mortality of Kraske's operation is from 12 to 15 per cent. Twenty-eight per cent. of Kocher's cases of extirpation of cancer of the rectum remain well from three to sixteen years after operation (W. W. Cheyne, "Brit. Med. Jour.," June 13, 1903).

XXX. ANESTHESIA AND ANESTHETICS

Anesthesia is a condition of insensibility or loss of feeling artificially produced. An **anesthetic** is an agent which produces insensibility or loss of feeling. Anesthetics are divided into—(1) *general anesthetics*, as amylene, chloroform, chlorid of ethyl, ether, bromid of ethyl, nitrous oxid, and bichlorid

of methylene; (2) *local anesthetics*, as alcohol, bisulphid of carbon, carbolic acid, ether spray, cocain, eucain, stovain, ice and salt, rhigolene spray, and ethyl chlorid spray.

Anesthesia may be induced by a general anesthetic to abolish the usual pain of labor and of surgical procedures; to produce muscular relaxation in tetanus, herniæ, dislocations, and fractures; and to aid in diagnosticating abdominal tumors, joint-diseases, fractures, and malingering.

Ether was first used as a surgical anesthetic by Crawford W. Long, of Georgia, in 1842, but he did not publish his cases until after William T. G. Morton, of Hartford, had given ether in public in 1846. Horace Wells gave nitrous oxid in 1844. Sir James Y. Simpson introduced chloroform in 1847.

Death-rate from Anesthetic Agents.—Sir Frederic W. Hewitt ("Anesthetics and Their Administration") combines the statistics of Julliard and Ormsby, with the following result:

Anesthetic.	Total Number of Administrations.	Total Number of Deaths.	Death-rate.
Chloroform	676,767	214	1 in 3,162
Ether	407,553	25	1 in 16,302

Hewitt regards the St. Bartholomew Hospital records as furnishing the most reliable statistics accessible. He takes them from 1875–1900. The fatality from chloroform was 1 in 1300; from ether (and gas and ether), 1 in 9319. It is to be noted that statistics covering many countries would indicate that chloroform becomes relatively safer in warm regions. In temperate regions it is relatively safer (compared with ether) in summer than in winter. Hewitt is of the opinion that ether is six times as safe as chloroform. Gwathmey ("Jour. Am. Med. Assoc.," Nov. 23, 1912) collects statistics from American sources. In 157,453 administrations of ether there were 28 deaths (about 1 death in 5623 administrations). In 16,390 administrations of chloroform there were 8 deaths (about 1 death in 2049 administrations).

Hewitt finds that during the last forty years only 30 fatalities are recorded as produced by nitrous oxid, and he thinks several of these should be excluded. It is practically certain, however, that many deaths, or at least some deaths, have not been recorded.

Seitz collected 16,000 instances of anesthesia by chlorid of ethyl, with 1 death. During a hospital experience of twenty-eight years I have seen anesthetics (particularly ether) given many thousand times. For five years I gave ether and chloroform for Prof. Keen. I have witnessed 3 deaths, each of which at the time was thought to be directly due to the anesthetic, and 1 of them was so caused. One death resulted from pouring a quantity of chloroform upon an Allis inhaler, the bandage of which was saturated with ether. At the time the chloroform was poured in the inhaler the patient had just been struggling and consequently was breathing deeply. One death resulted from giving ether on a thick cone made of several towels with paper between the folds. The towels were saturated with ether, the patient got no air at all, and was asphyxiated, as she might have been had the cone only been wet with water. The third case was a man who had an impacted hip fracture. He became cyanotic under ether while the impaction was being pulled apart and died. The death was supposed to be due to ether, but necropsy discovered fat emboli in the brain and lungs.

Preparation of the Patient.—Whenever possible prepare a patient before administering a general anesthetic, and prepare him, if the case admits of it, during two or more days. Heart disease is not a positive contra-indica-

tion to surgical anesthesia. It is quite true that anesthetics are dangerous to people with fatty hearts, but shock is also dangerous, and the surgeon stands between the Scylla of anesthesia and the Charybdis of shock. Gallant truly says that not enough attention is paid to the "character of the pulse and action of the heart before operation, by which to compare its work during anesthesia, and after the operation is over, and this neglect leads to unnecessary stimulation and overdriving a heart which is doing its average best."[1] Always examine the urine if the nature of the case allows time. If albumin is found, operation is not contra-indicated, but the peril of anesthesia is greater, and certain dangers are to be watched for and guarded against. If much albumin is present, postpone operation except in emergency cases. If sugar is found, the danger is considerable, as diabetic coma occasionally develops. The percentage of sugar does not determine the amount of danger. Coma may arise when only a little sugar is present, and may not arise when there is a considerable amount. The presence of aceto-acetic acid is more ominous than is the presence of sugar. Empty the intestinal canal by purgation a number of hours before anesthetization. It is well to give the bowel six to twelve hours' rest before operation. The usual custom is to give a saline cathartic the evening before operation and an enema early on the morning of the operation. Frequently the nature of the case or the necessity for haste does not permit of preliminary emptying of the intestine by the administration of cathartics. During the twenty-four hours preceding operation food should be taken in small amounts and in forms easily digestible. During the day or so before operation there is usually impaired digestion, and no undue strain should be put upon the stomach. In the morning allow no breakfast if the operation is to be performed at an early hour, but if the patient is very weak, order a little brandy and beef-tea. If the operation is to be about noon, give a breakfast of beef-tea and toast or a little consommé; *never* give any food within three hours of the operation, but brandy is admissible if stimulation is required. If the stomach is not empty at the time of operation, vomiting is almost inevitable, and portions of food may enter the windpipe; if the stomach contains no food, vomiting is far less likely to happen; and even if it occurs and vomited matter should enter the windpipe, it may do little harm, as it consists chiefly of liquid mucus. In cases of intestinal obstruction in which there has been stercoraceous vomiting there is much danger that vomiting will occur during anesthetization. In some cases of intestinal obstruction, during the administration of the anesthetic and during the anesthetic state, a stream of stinking brown fluid may flow without effort from the mouth. Vomiting or regurgitation of stercoraceous material is profuse, sudden, and dangerous. It may flood the bronchial tubes during inspiration and cause death by suffocation. In a case in which stercoraceous vomiting has occurred wash out the stomach before administering the anesthetic. If a patient with intestinal obstruction is too weak to permit lavage, a local anesthetic should be used instead of a general anesthetic. Vomiting while the patient is under the influence of an anesthetic is dangerous in any case, because of the great cardiac weakness which precedes and follows it. If a patient sleeps well the night before an operation, he will probably take the anesthetic better than if he sleeps poorly. Effort should be made to obtain a night's sleep. An excellent expedient is a hot ammonia bath, followed by a rub-down with weak alcohol.[2] It may be necessary to administer trional or bromid. About fifteen minutes before giving the anesthetic let the patient drink a glass of hot water. Water protects the stomach from the irritant effects of any anesthetic which may be swallowed. Before giving the anesthetic see that artificial teeth are removed and that the patient does not have a piece of candy or a chew of tobacco

[1] "Medical Record," Feb. 2, 1899. [2] A. Ernest Gallant, "Med. Record," Dec. 30, 1899.

in the mouth. Always have a third party present as a witness, because in an anesthetic sleep vivid dreams often occur, and erotic dreams in women may lead to damaging accusations against the surgeon. Place the patient recumbent. The effort should be to place him in as comfortable a position as possible if this position is consistent with operative necessities. Put a small pillow under him, so as to support the normal lumbar curve and prevent postoperative backache. See that the clothing is loose, particularly that there is no constriction about the neck and abdomen. Do not have the head high unless this position is demanded by the exigencies of the operation. The anesthetist must have a mouth-gag and a pair of tongue forceps at hand. It is very wrong to say that a mouth-gag and tongue forceps are never necessary. It is quite true they are often used when not needed, but this does not justify us in being without them when they are needed, and they may be needed very badly. The anesthetist should also have a pair of artery forceps and some small gauze sponges to swab out the mouth and throat. A hypodermatic syringe in *working* order, and solutions of strychnin, atropin, and brandy are to be in an accessible place, oxygen must be ready for administration, and it is well to have an electric battery adjacent. Accidents, it is true, are rare, but they may happen at any time, and hence the surgeon should always be prepared for them. Any danger which arises must be met promptly and decisively, or action will be of no avail. Many surgeons give a hypodermatic injection of morphin a short time before operation to steady the heart, to prevent vomiting during anesthetization, to shorten the stage of excitement, to prevent rigidity, and to aid the bringing about of insensibility with very little of the anesthetic. This method has been tried by many during the last forty odd years. It is used in drunkards (as their muscles tend to remain rigid in the anesthetic state), in those whom it is difficult to make completely unconscious, in neurotic individuals, and in badly frightened subjects. Its greatest use has been in operations about the mouth and face, for in these procedures an anesthetic was given on a towel or inhaler, was of necessity given intermittently, and a preliminary dose of morphin was found to keep the patients from rousing during the intervals. At present intratracheal anesthesia does away with the need of morphin in operations about the mouth and face. There are objections to giving morphin before anesthesia, and its use should be the exception and not the rule. It should not be used in children, in cases of stupor, or in cases in which the respiratory center is disordered. It depresses the respiration, lowers temperature, and thus perhaps increases operative shock, interferes with the pupillary phenomena of anesthesia, delays awakening from the anesthetic sleep, adds to subsequent abdominal distention and headache, and actually favors postanesthetic vomiting. Hewitt ("Anesthetics and Their Administration") says that several recorded fatalities were due to the combination. If the surgeon determines to give morphin, he gives $\frac{1}{6}$ to $\frac{1}{4}$ gr. twenty minutes before the anesthetist begins to give the anesthetic. Hewitt (Ibid.) says: "The anesthetic should be given until the usual signs of anesthesia commence to appear. . It should then be discontinued for a few moments and only reapplied as occasion may require. As little as possible of the ether or chloroform should be subsequently administered; the conjunctival reflex should be retained." In the clinic of the Jefferson Hospital the elder Gross long used as a routine the preliminary administration of opium, but during his later years he used it exceptionally. His successor, the younger Gross, used morphin hypodermatically exceptionally. In some cases we may anticipate trouble from the anesthetic. Cyanosis may occur in drunkards; in fat, thick-necked individuals of the Major Bagstock type, who are short of breath and congested in appearance; in individuals with some disease of the lungs, bronchi, pharynx, larynx, or trachea (empyema, emphysema, chronic bronchitis, croup, cancer of the larynx, etc).;

in individuals suffering from fatty heart or valvular incompetence. Buxton points out that an individual without teeth and with stenosis of the nares is apt to become cyanotic under an anesthetic, because the lips and pillars of the fauces are drawn in like valves during inspiration.

Ether and Chloroform.—The two favorite anesthetics are ether and chloroform. Only the very best ether or chloroform should be used. It is a good plan, in order to lessen bronchitis, to mix with ether turpentine of Pinus pumilio in the proportion of 20 drops to $6\frac{1}{2}$ oz. (Becker, in "Centralbl. f. Chir.," June 1, 1901). Chloroform is more dangerous than ether in general cases, though it is more agreeable, less irritant to the lungs and kidneys, and quicker in its action. Chloroform, compared to ether, is relatively safer in warm than in cold countries. In fact, in the tropics it is a matter of considerable difficulty to use ether because of its great volatility. It should, however, be noted that Squire used ether successfully when the temperature was 120° F. in the shade ("Lancet," vol. i, 1913). Chloroform is preferred in campaigns, because less is required and transportation is easier. Recovery from chloroform is quicker and quieter than that from ether, but chloroform vomiting lasts longer than ether vomiting. Chloroform may induce sudden and even fatal syncope. Hare's experiments on animals indicate that chloroform may kill by respiratory failure occurring secondarily to failure of the vasomotor center; but certain it is that clinically a danger of chloroform is paralysis of the heart, and this condition may come on so rapidly that death may occur almost before an attempt can be made to save life. Leonard Hill has proved that most chloroform deaths that take place after considerable of the anesthetic has been taken arise from paralytic distention of the heart. Sudden death, when inhalations of chloroform have just commenced, may be due to the irritant vapor acting on the nasal mucous membrane, exciting a nasal reflex, and powerfully stimulating cardiac inhibition. If ether produces danger it does so usually through the respiration, and not the heart, and there is generally time to undertake means of resuscitation, which means are apt to be successful. Chloroform is preferred to ether by many surgeons for children under ten years of age, in whom ether causes a great outflow of bronchial mucus, which may asphyxiate; for people over sixty, entirely free from myocardial disease, at which age most persons have some bronchitis, and ether chokes them up with mucus. Ether also irritates the kidneys, which at the latter age are apt to be weak or diseased. Personally, I give ether even to infants (if they are free from bronchitis) and to old subjects without marked respiratory trouble. Chloroform is given if the actual cautery is to be used about the face, neck, or mouth, because ether vapor may take fire and chloroform vapor will not. Chloroform is preferred for labor cases, when moderate anesthesia only is required, and was preferred for operations on the mouth and nose before the advent of intratracheal anesthesia. In cleft-palate operations chloroform is usually preferred, because it causes but little cough and salivary flow. In ligation of a large artery which is overlaid by a vein ether greatly enlarges the vein, but this is no real embarrassment to an experienced surgeon. In goiter operations ether will decidedly enlarge the veins. Most goiters may be, and many should be, removed with the aid of local anesthesia only. Chloroform is particularly dangerous when there is myocardial disease, and is apt to produce cyanosis and embarrassed respiration. In valvular heart disease chloroform is more dangerous than ether, and even in functional heart trouble it is an undesirable anesthetic. It should not be used in those who smoke or chew tobacco to excess, or who overindulge in coffee or alcohol. Chloroform is more dangerous in shock than ether. A patient in dangerous shock requiring operation should, if possible, have the nerves coming from the part injected with cocain so as to prevent

further shock by introducing a "physiological block"—Crile (see page 262). Chloroform is preferred for patients with difficult respiration from any cause other than heart disease (in emphysema, bronchitis, or pulmonary tuberculosis), and for patients with kidney disease. I am convinced that etherization is sometimes responsible for a latent area of pulmonary tuberculosis becoming active. Some surgeons do not use ether in abdominal operations because they believe it may cause persistent oozing of blood, but this view is not in accord with the author's experience. Ether is the best and safest anesthetic for general use. It is much safer than chloroform in valvular disease and functional heart trouble. It is dangerous in myocardial disease, but not nearly so dangerous as chloroform. In valvular disease without heightened arterial tension it is reasonably safe, but in valvular disease with heightened arterial tension it is dangerous. Ether is dangerous when atheroma exists. Both ether and chloroform may induce changes in the blood.[1] In practically all cases they produce a diminution of hemoglobin and leukocytosis. In some cases they produce alteration in the shape of the corpuscles. These changes are especially marked in anemic blood. Ether produces distinct leukocytosis, probably toxic in origin. Both ether and chloroform seem to lessen the phagocytic activity of leukocytes, and hence to lower vital resistance (Ferguson, in "New York Med. Jour.," May 11, 1912). These blood changes indicate that prolonged anesthesia must militate against recovery from a severe operation. If a patient's hemoglobin is below 30 per cent., a general anesthetic should not be given. During the state of anesthesia the temperature drops from 1 to 3 degrees or more, hence the patient should be carefully covered during the operation. The question as to the effect of ether on the kidneys is much disputed. Most surgeons believe that it tends to cause albuminuria or increase existing albuminuria. Nitrous oxid is very dangerous when there is vascular degeneration, and it may induce apoplexy. It is also dangerous if the air-passages are narrowed as by a goiter. In giving ether or chloroform the administrator must devote his undivided attention to the task. He must note every symptom, must order or carry out proper treatment for complications, and must keep the operator informed as to the necessity for haste. The anesthetist must be a man who has a wholesome respect for ether and chloroform, although not afraid of them.

Can an anesthetic be administered to a sleeping person without waking him? I know that chloroform can be so given, for I have succeeded in giving it to a child without breaking the slumber. Probably, in most cases, an attempt will fail, but in some it will succeed. Stone ("Cleveland Med. Jour.," Jan., 1902) reports successful administration to sleeping children and also the chloroforming of a resident physician while asleep. Paugh ("Jour. Am. Med. Assoc.," May 18, 1901) reports three successes with children. Ether, because of the irritant nature of its vapor, would be more apt to arouse a sleeper than chloroform.

Administration of Chloroform.—Chloroform should be given only by a highly trained man. In fact, safety in giving chloroform is dependent upon skill and experience more than in giving ether. No one should think of allowing anyone but a physician to give chloroform. The most dangerous period is when the patient is incompletely anesthetized, but is going under. Most deaths happen at this time. In administering chloroform have at hand a mouth-gag, tongue forceps, artery forceps, small gauze sponges, a clean towel, a hypodermatic syringe, solutions of strychnin, atropin and brandy, an electric battery, and a can of oxygen. Use only *pure* chloroform. The

[1] See the author on the "Blood-alterations of Ether-anesthesia," "Medical News," March 2, 1895, and also the author and Kalteyer in "The Proceedings of the American Surgical Association for 1901."

patient must be recumbent. No special inhaler is required, but the drug may be given upon a thin towel, a napkin, or a piece of lint. The mask of Skinner (Fig. 791) is very useful. Junker's inhaler (Fig. 792) is used by many anesthetists. In operations about the face Souchon's instrument is serviceable. Souchon's apparatus is so arranged that chloroform may be given through a tube which is introduced through the nose, the instrument being well out of the way of the operator. Some surgeons cocainize the nares before giving chloroform, so as to prevent the supposedly dangerous nasal reflex (Rosenberg). It is advisable to smear the lips and face with cosmolin to prevent blistering. The chloroform vapor must be well mixed with air. The chloroform is sprinkled on the fabric from a drop-bottle. Raise the napkin well above the mouth, add 5 drops of chloroform, and tell the patient to take deep and regular breaths, but do not tell him to breathe forcibly. Forcible respiration may lead to cessation of respiration. Add a few more drops of chloroform, and when the patient grows so accustomed to it that it does not choke, turn the wet part of the fabric toward the face and place it near the mouth; do not touch the mouth with the wet lint, because it will blister. If the drug is given *gradually*, struggling is not usually violent or prolonged. Never pour on a large amount at one time. Keep the lower jaw pushed forward during the time the chloroform is being given. Cough

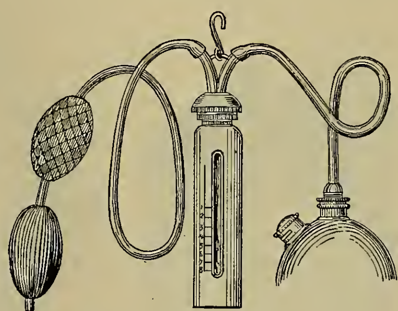

Fig. 792.—Junker's inhaler.

and vomiting at this time mean that the vapor is too strong. During the stage of excitement do not suspend the administration of chloroform unless respiration becomes difficult, in which case suspend it until the patient takes one or two respirations. If the patient struggles, do not hold him, and push the administration of the drug. He holds his breath while struggling, and as struggling ceases takes full, deep breaths. If the inhaler is saturated with chloroform, he may inhale a dangerous amount during the deep respiration after struggling. Chloroform given in considerable amount when the patient is breathing deeply from the effects of ether is unsafe. If chloroform is given subsequent to anesthetization by ether, it should be given gradually and well mixed with air. When the patient becomes anesthetized, give just enough of the drug to keep him so. While a patient is taking chloroform hiccup usually means that vomiting is going to occur. If vomiting occurs at this time more chloroform must be given to abolish the reflexes. Deep and sighing respiration and repeated swallowing indicate that more of the anesthetic is required. Stop the administration or give very little when shock becomes evident or when there is profuse hemorrhage. Chloroform vapor is not inflammable, hence it is safer than ether when a hot iron is to be used about the face and when there is a lighted lamp or a stove in a small room; but the presence of a naked gas-flame decomposes chloroform

into irritant products of chlorin ($COCl_3$), which cause the patient and the surgeon to cough.

Chloroform and Oxygen.—The use of this mixture was suggested by Neudorfer. Some anesthetists advocate the mixture of chloroform and oxygen, asserting that it does not produce spasm of the glottis or muscles of respiration, that it does not produce cyanosis or weakness of circulation, that it does not irritate the kidneys, is safer to life than pure chloroform, and is less often productive of severe and prolonged vomiting. These alleged advantages are probably stated with rather undue emphasis, although I do believe the mixture has less tendency to produce cyanosis than has the pure drug, does not so often induce vomiting, and is somewhat safer. Hewitt does not think that the method offers any "special advantages" ("Anesthetics and their Administration," by Sir Frederic W. Hewitt). If this method is used, a bag containing oxygen is attached to the hand-bellows attachment of a Junker inhaler, and oxygen is forced through the chloroform and flows to the face-piece.

Administration of Ether.—The administration should not be intrusted to a novice. The anesthetist should be one of your most trusted men. I do not believe in allowing a nurse to give ether. She cannot have sufficient knowledge to observe incipient trouble, to anticipate outward effects, and to

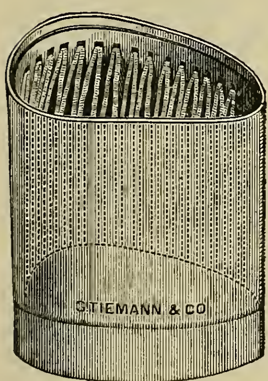

Fig. 793.—Allis's ether inhaler.

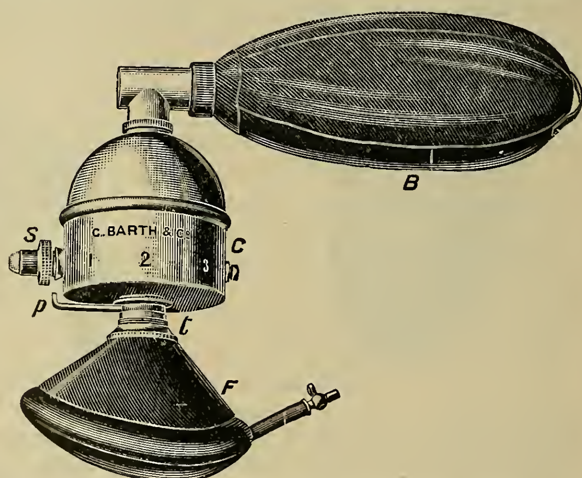

Fig. 794.—Clover's portable regulating ether inhaler.

at once do the correct thing when difficulty arises or calamity impends. The moral responsibility and the legal responsibility demand that a physician give the ether. Ether is best given from a partially open inhaler. The most satisfactory appliance is Allis's inhaler (Fig. 793). This inhaler secures a plentiful supply of air. Before being used the metal frame is scalded, dried, and threaded with a clean gauze bandage. The end of the frame which is to be toward the mouth is covered with one layer of gauze. The frame is then inserted in a clean metal case and the case is wrapped in a clean towel. The drug is given drop by drop, the drops following each other in regular sequence. This is known as the *drop method*. The drop method is the safest plan and the most comfortable to the patient. Instead of Allis's inhaler a piece of gauze or an Esmarch inhaler may be used. Some surgeons prefer closed inhalers. The Clover inhaler (Fig. 794) is popular in England. *F* is the face-piece; *C*, a reservoir of ether through which the air-current passes; *B* is an India-rubber bag. In this apparatus there is no provision for the entrance of fresh air. By turning the reservoir *C* on the tube *t* the amount of current passing over the ether can

be regulated. When this apparatus is used, the ether vapor breathed into the lungs is expired into the bag and is rebreathed. This inhaler, if used by a skilful man, is very useful; but any lack of watchfulness or skill will permit of cyanosis, and the very young, the senile, the anemic, and feeble are best anesthetized by the drop method described above.

An admirable detailed account of anesthetization by the closed method will be found in Sir. Frederic W. Hewitt's treatise on "Anesthetics and Their Administration," and in Mr. Dudley W. Buxton's treatise on "Anesthetics, Their Uses and Administration." When giving ether, have at hand the same drugs and appliances as when chloroform is given, and keep the lower jaw pushed forward during the administration. When using Allis's inhaler, take every care that none of the ether runs through on to the face and into the eyes. If it does it will irritate and perhaps blister. Even the vapor irritates the eyes, and boric acid solution should be used now and then during the administration to flush out the conjunctival sacs. It is wise to grease the face and lips with cosmolin. Place the dry inhaler over the mouth and nose, let the patient take several breaths, that he may gain confidence, begin to drop ether into the inhaler, let the patient take several more breaths, and so on, gradually increasing the rapidity with which the drops of ether are given. If he tends to struggle, diminish the amount of ether for a time, but do not hold him. Do not tell him to breathe forcibly. Forcible breathing is liable to cause a cessation of respiration. Never suddenly add a large amount of the anesthetic: it causes coughing and often vomiting. When the patient becomes thoroughly anesthetized, give a very little ether as often as is required to maintain unconsciousness. When bleeding is profuse or shock is marked, suspend the administration of ether or give very little of it. If he rolls his eyes from side to side, if the respirations are deep and sighing, if there are repeated movements of swallowing, more anesthetic should be given (Tarnowsky). Hiccup is often preliminary to vomiting, and always means that the reflexes are returning. If a hot iron is to be used about the face, remove the inhaler and fan away the ether before bringing the cautery near. Have any light set high up, as ether vapor is heavier than air, and no explosion is possible until it reaches the level of the flame. If the vapor takes fire, cover the patient's mouth and nose with a towel.

The patient should be kept in a condition in which he feels no pain, makes no movement, and is not rigid. In this condition the cutaneous reflexes are abolished, the breathing is regular and quiet, the color is good, and the pupils react to light, though slowly. Just enough anesthetic must be given to cause the patient to pass into this condition and remain in it. To give any more is to poison him. The amount necessary varies with the individual and the operation, and requires skill, experience, and attention on the part of the anesthetist.

The old idea that we must poison a man into dangerous coma has been abandoned. When the breathing becomes louder, more rapid, or spasmodic, it means that reflexes are returning, and a little more anesthetic should be given.

Ether and Oxygen.—This mixture is useful in certain cases in which respiratory difficulty exists, particularly in empyema. If during the administration of ether cyanosis tends to occur, it is often advantageous to give oxygen with the ether. The process of anesthetization by ether and oxygen is somewhat slower than by ether vapor mixed with air. It can be given by inserting beneath the Allis inhaler or pushing deep down into it, from above, a tube attached to a reservoir of oxygen and from which a stream of oxygen emerges.

Intratracheal Insufflation Anesthesia (Method of Meltzer and Auer).—A flexible elastic tube much smaller in diameter than the trachea is

carried down almost to the tracheal bifurcation. When air is forced in it emerges between the tube and the trachea. The addition of ether vapor to the air makes the maintenance of anesthesia easy. Ether can thus be administered by means of a tracheal tube, a Wolff bottle to contain the ether, and a foot-bellows. I have had it given in this way a number of times. Elsberg's apparatus (see Fig. 570) permits of the most desirable method.

The patient is first anesthetized by the ordinary method. When unconscious the head is dropped back over the end of the table, and the tube is passed into the trachea "under the guidance of the eye by means of a Jackson direct laryngoscope" (see Fig. 562). (See Brewer, in "Keen's Surgery," vol. vi.) In this form of anesthesia the stream of air carries off ether vapor and prevents accumulation in the tubes.

A degree of anesthesia necessary to maintain muscular relaxation will not apparently cause dangerous symptoms. If the ether is given for a long time in unnecessarily large amounts danger may be reached, but it is attained gradually and not suddenly and gives warning. If there should be an ominous fall in blood-pressure and respiratory failure, cut out the ether vapor and use the apparatus for artificial respiration. A patient remains very still under this method of anesthesia, awakes rapidly from it, and suffers little from shock and postoperative vomiting. Nitrous oxid and oxygen have been given by this method. Meltzer is studying chloroform so used ("Keen's Surgery," vol. vi). In operations about the head, mouth, and neck insufflation anesthesia keeps the anesthetist out of the operator's way. In operations about the mouth the method prevents the inhalation of blood or vomit. In goiter operations it is a safeguard against sudden suffocation. In intrathoracic operations it serves to prevent collapse of the lung. After the operation all ether vapor is driven out of the lungs by a stream of fresh air. Peck ("Annals of Surgery," July, 1912) maintains that the insufflation method is safe if certain rules are carefully followed. These rules are to avoid excessive pressure (which might rupture air-cells), be sure not to spray liquid ether into the tracheal tube, do not carry the tube into the gullet or beyond the tracheal bifurcation, and do no damage by rough introduction. Meltzer (Loc. cit.) refers to 3 deaths.

Rectal Etherization.—Pirogoff suggested this method in 1847 and Roux employed it the same year. The method is only used in operations about the face, tongue, nasopharynx, pharynx, mouth, and larynx; in other words, in cases in which, were the ether given by inhalation, the operator and anesthetist would interfere with each other. The rectum should be emptied by a purgative enema the day before the operation, and again the morning of the operation, and a short time before giving the ether the rectum should be irrigated with warm salt solution. A dose of laudanum is given a few hours before, or an injection of morphin and atropin twenty minutes before the administration of the ether. We should employ an apparatus of the type of Buxton's, which prevents liquid ether from passing into the rectum.

A tube containing ether is set in a vessel containing water at a temperature of 122° F. The ether tube is joined by a glass tube and rubber pipe to a glass globe, and the globe is connected by a rubber pipe to the tip, which is inserted into the rectum. If ether vapor condenses into liquid in the glass globe the globe should be at once emptied. During the administration abdominal distention occurs from unabsorbed ether, and from time to time the administration should be suspended temporarily to permit the gas to escape, otherwise too much will be given and prolonged stupor and postoperative colic may result. It takes much longer to obtain unconsciousness by rectal administration than by inhalation. The method must never be used if the intestines are irritated or inflamed (Dumont, in "Corr-Bl. f. Schweizer Aerzte," Dec. 15, 1908). The method has never come into general use. It irritates the large

intestine, often produces colic, and sometimes is said to lead to protracted stupor ("Anesthetics and Their Administration," by Sir Frederic W. Hewitt). In some cases we can begin the ether by inhalation and shift to the rectal administration when ready to operate. I agree with Baum that the method is more dangerous than the inhalation method. After one of Baum's cases intestinal hemorrhage occurred; in another, gangrene and perforation ("Zentral. für Chir.," March 13, 1909). Dudley W. Buxton, however, has employed it in many operations about the face, mouth, and larynx, and in some operations for empyema, and commends it. Rectal etherization does not produce a sense of suffocation, the stage of excitement is short, and struggling is trivial or absent. Intratracheal insufflation anesthesia seems to have practically done away with all need for rectal anesthesia.

Intravenous Etherization (Infusion Anesthesia).—This method was devised by Burkhardt, of Würzburg, and is still on trial. A $7\frac{1}{2}$ per cent. solution of ether in normal salt solution is employed by Rood ("Lancet," March 23, 1912). He found that a 10 per cent. solution causes hemolysis and a 5 per cent. solution is inadequate. About three-quarters of an hour before operation he gives a hypodermatic injection of $\frac{1}{6}$ gr. of morphin, $\frac{1}{100}$ gr. of scopolamin, and $\frac{1}{100}$ gr. of atropin. When ready to operate, a vein is selected, exposed and opened, and the cannula is introduced. The solution is warm. From $\frac{1}{2}$ to 1 pint of the fluid is run in and anesthesia should be secured in from three to five minutes. Anesthesia is maintained by running in a constant succession of drops. If anesthesia becomes too deep the rate of flow is lessened, and vice versâ. This method of anesthesia keeps the anesthetist out of the way in operations on the head, neck, and mouth. It is claimed that it enables us to measure the dose of anesthetic much more accurately than does the respiratory plan, and that by it we avoid irritation of the mucous membrane of the respiratory tract. The respiration must be watched just as carefully as in respiratory anesthesia. Rood ("Brit. Med. Jour.," Oct. 21, 1911) has had 136 cases and no bad results.

Hedonal has been used for infusion anesthesia. It was suggested by Federoff, of St. Petersburg. Mr. Page, of London, has reported 75 cases ("Lancet," March 23, 1912). He uses a .75 per cent. solution in normal salt solution and gives it continuously. Ward ("Lancet," March 23, 1912) has reported a death from it.

Anesthetic State from Ether or Chloroform.—The inhalation of an anesthetic produces irritation of the fauces, often some cough, a profuse secretion of mucus, acts of swallowing, dilatation of the pupils, flushed face, and sometimes struggling (especially in children and in drunkards). If at the start the vapor is given in concentrated form, cough will be violent and will cause cyanosis. If the anesthetic is given gradually the cough soon ceases, the respirations become rapid and often convulsive, the pulse becomes frequent, and the patient passes into a condition of active intoxication with preservation of sight and touch, loss of hearing and smell, diminution of pain and sensibility, and often with illusions or hallucinations. In this stage the patient may struggle, and while efforts are being made to hold him, cyanosis may occur. From the stage of excitement just alluded to, many subjects (strong men and drunkards) pass into a stage of rigidity in which the muscles become firmly fixed, the breathing is impeded, the respirations are stertorous, and the face is bluish and congested. Too rapid forcing of the anesthetic tends to cause rigidity, and a skilled anesthetist endeavors to avoid its production, because it is dangerous. The next stage is one of insensibility; the pupils are contracted and react sluggishly to light. If anesthesia is deep the contracted pupils will not react to light; if anesthesia is profound the pupils dilate, but will not react to light. The conjunctival reflex

is gone; the lids are closed; if the arm is lifted and allowed to fall, it drops as a dead weight; the skin is cool and moist and often wet with sweat; the respirations are easy and shallow; the pulse is slow, and there is complete unconsciousness to pain. The loss of conjunctival reflex is the usually accepted sign that the patient is unconscious. In a young child this reflex is soon exhausted by touching the eye, and the sign is unreliable. If a baby is to be anesthetized, the administrator places his finger in the infant's hand. The child grasps the finger, and relaxes its grasp when unconscious.

Always bear in mind that dilated pupils reacting to light and associated with preserved conjunctival reflex mean that anesthesia is not complete; that contracted pupils reacting to light and without conjunctival reflex mean moderate anesthesia; that contracted pupils not reacting to light and without conjunctival reflex mean deep anesthesia; that dilated pupils not reacting to light and associated with lost conjunctival reflex mean dangerously profound anesthesia. Sudden dilatation with fixation is always very ominous. The pupillary phenomena are very valuable when present, but unfortunately they are absent at some stage of the anesthesia in many cases. Inequality of the pupils is not unusual and fixation of one pupil or of both may occur. A preliminary dose of morphin or atropin interferes with the pupillary phenomena. Weak pulse and pallor may be due to nausea, but always require instant attention. Vomiting may be due to forcing strong vapor upon the patient, but may also be due to his partially emerging from a state of insensibility.

Watch the pulse carefully to see if it becomes very weak, irregular, abnormally slow, abnormally fast, or if it suggests a fall of blood-pressure. Syncope may be due to nausea, shock, hemorrhage, or the giving of too much of the drug. Watch the respiration, and do not forget that the chest walls and belly may move when no air is entering the lungs; hence always *listen* to the breathing. *Cyanosis* is a dusky or bluish discoloration of the skin. This condition indicates want of oxygen in the blood. The individual may have been cyanotic or predisposed to cyanosis to start with; cyanosis may be due to pressure; to cough early in the administration; to struggling during the stage of excitement; to gathering of mucus in the respiratory tract; or to rigid fixation of the respiratory muscles. It may also be due to obstruction of the air-passages by some foreign matter, as blood or vomit, lodging in the bronchial tubes, windpipe, larynx, or pharynx; falling back of the tongue (*swallowing of the tongue*); closure of the epiglottis; or to the glottis being pushed against the pharyngeal wall by bending the head forward. Some patients with occluded nostrils may fail to get enough air because of closure of the lips. A patient may, while taking an anesthetic, lie perfectly quiet and appear to "forget to breathe." Ether and chloroform mitigate the causal mental phases of shock, but neither drug keeps nerves from conveying stimuli and each produces a fall of blood-pressure, chloroform directly by its action on the vasomotor center, ether by overstimulation of the vasomotor center (Buxton, in "Proceedings of the Royal Soc. of Med.," April, 1909). Each produces a fall of temperature. Buxton heartily condemns the once common belief "that evidences of shock during a surgical operation are a proof that an insufficient quantity of the anesthetic has been given and that the symptoms of shock can be abrogated by increasing the depth of the narcosis" (Ibid.). Heavy anesthesia by ether or chloroform produces or adds to shock. Shock is manifested by deathly pallor, weak, rapid, and irregular pulse, slow respiration, cold extremities, and a drenching sweat. Edema of the lungs occasionally arises during or after anesthesia.

Treatment of Complications.—*Vomiting* due to too much anesthetic is corrected by giving a few breaths of air; vomiting due to incomplete anesthesia is amended by giving more of the vapor. While the patient vomits hold the head

over the edge of the bed, and when vomiting ceases separate the jaws with the gag, and wipe out the vomited matter, mucus, and saliva. *Shock* is treated by diminishing the amount of the anesthetic that is being given, by the hypodermatic injection of atropin (atropin is particularly useful when there is a profuse sweat), by the administration of hot saline fluid by the rectum, by surrounding the patient with hot-water bottles, or by wrapping him in hot blankets, and by lowering the head of the bed. Syncope is sudden cerebral anemia and is usually due to a reflex cause. A tendency to *syncope* requires lowering of the head of the bed, suspension of the anesthetic, and hypodermatic injection of strychnin. In *extreme syncope*, which is most apt to occur from chloroform, do not wait for breathing to cease, but suspend the anesthetic, lower the head of the bed, open the mouth with the gag, catch the tongue, and make rhythmical traction while an assistant is making *slow* artificial respiration. If the patient does not *at once* improve, invert him completely, holding him by the legs and continuing artificial respiration by compressing the sternum (Nélaton). By continuing artificial respiration the blood is urged on through the heart. Give hypodermatic injections of atropin, ether, or even of ammonia. Put mustard over the heart and spine. Employ faradism to the phrenic nerve (one pole to the epigastric region, the other to the right side of the root of the neck). Let fresh air into the room, put hot-water bottles around the legs, apply friction to the extremities, wrap the patient in hot blankets, give an enema of hot salt solution, and hold ammonia to the nose. In some cases of anesthetic poisoning *direct heart massage* has been successfully employed. The method was suggested by Schliff in 1874. Frazier was operating for hydrocele when the patient's respiration ceased and his pulse disappeared. Frazier at once opened the abdomen and, with one hand on the chest wall and the other against the diaphragm, "massaged the heart at the rate of 15 to 20 movements a minute." In about two minutes cardiac contractions were perceptible. In about eight minutes resuscitation was complete ("Jour. Am. Med. Assoc.," May 20, 1911). In Conkling's case there was a chest wound exposing the lung. The heart ceased to beat. The surgeon grasped the heart between the fingers and made compressions. In less than a minute he detected a thrill, and in a few seconds more regular pulsation began ("New York Med. Jour.," Sept. 2, 1905). In Sencert's successful case an operation was being done for gall-stones when collapse occurred, and the surgeon stroked and kneaded the heart through the diaphragm. In a case recorded in the "Brit. Med. Jour.," Nov. 18, 1905, respiration and pulse had ceased three minutes when the abdomen was opened and the heart was kneaded. Recovery ensued. Müller, of Hamburg, advocates exposing and opening the pericardium to perform massage, introducing oxygenated salt solution into a vein, opening the trachea, and performing artificial respiration. Frazier ("Progressive Medicine," March, 1911) publishes statistics of 50 collected cases. These figures indicate that the subdiaphragmatic method is more successful than either the direct method or the transdiaphragmatic method. The table is as follows:

	Successful.	Partially successful.	Failures.	Total.
Direct............	2	8	18	28
Transdiaphragmatic..	0	1	2	3
Subdiaphragmatic....	8	5	6	19
	10	14	26	50

Leonard Hill holds that in the failure which arises *soon after administration of chloroform is begun* the trouble is due to vasomotor paralysis with starvation of the nerve-centers. In such a case he applies abdominal compression and

inverts the patient, making artificial respiration at the same time. In the failure which occurs after *considerable chloroform has been taken* there are paralytic distention of the heart, fulness of the venous system, and loss of the compensations for the hydrostatic effects of gravity. In such a condition empty the distended heart of venous blood by raising the patient into an erect position, and after a moment place him recumbent and make artificial respiration.

Forgetting to breathe is met by removing the inhaler and waiting a moment; a breath will usually be taken soon; but if it is not taken, somewhat forcibly knead the structures in the arm-pit. If this fails, open the mouth and pull forward the tongue; this causes a reflex inspiration. Cyanosis is practically not encountered when oxygen is given with ether or chloroform. *Cyanosis*, if slight and due to cough or struggling, is met by removing the inhaler while the patient takes a breath or two of air. If position is responsible for cyanosis, correct it. In empyema, lying upon the sound side may produce it. Obstruction to breathing may be due to bending down the head. If due to stenosis of the nares in a person without teeth, hold the lips apart with a finger. If due to collection of mucus, wipe the mucus out of the mouth by means of bits of gauze firmly clamped in forceps; raise the shoulders, extend the head and place it on its side in order that mucus may run out of the angle of the mouth; and give a dose of atropin hypodermatically. If the amount of mucus is large and the secretion is persistent, it may be necessary, especially in children, to empty the respiratory passages by inverting the patient. In cases of excessive bronchial secretion we fear the development of pulmonary edema or postoperative bronchopneumonia.

Dudley W. Buxton points out that duskiness will often pass away if ether is removed, one or two inhalations of chloroform given, and ether then continued. If in any case cyanosis is severe or grows worse, suspend the drug, dash cold water in the face, force open the jaws, pull forward the tongue, make artificial respiration until a breath is taken, and then give oxygen for a time. If these means fail, stretch the sphincter ani and bleed from the external jugular vein. If a breath is not now taken, do tracheotomy. In respiratory or heart failure forced artificial respiration by Fell's method is of great value (see page 896). The pulmotor, if at hand, enables the surgeon to maintain regular artificial respiration for an indefinite time (see page 867). *Swallowing the tongue* is corrected by pulling the tongue forward. If it tends to recur, lay the head upon its side or keep the tongue anchored with forceps. *Closure of the epiglottis* is corrected by pulling the patient's head over the edge of the table and pushing strongly back upon his forehead. This maneuver lifts the hyoid bone, and with it the epiglottis. The epiglottis can be lifted by passing a spoon-handle or the index-finger over the dorsum to the base of the tongue and pressing forward. If, in obstruction to respiration, the above means fail, make artificial respiration at once (see page 864); if obstruction continues, perform tracheotomy.

Edema of the lungs is treated by instant venesection, the inhalation of nitrite of amyl, and the administration of stimulants and nitroglycerin hypodermatically. Sometimes during the anesthetic state the muscles of the belly become very *rigid*, a condition which greatly interferes with an abdominal operation. It may arise during cyanosis, and if so caused is amended, as cyanosis abates under proper treatment. In some cases it is due to the fact that sufficient anesthetic has not been given. If the air-passages are obstructed before operation, abdominal rigidity is apt to arise. In some cases it seems impossible to overcome it with ether. In such a case, if the anesthetist is a trusted man, anesthetize the patient with gas and ether and then give chloroform (Blumfield, in "Lancet," May 31, 1902).

The Reaction from Anesthesia.—When ether or chloroform is given, a considerable quantity is swallowed and either drug irritates the stomach and creates nausea and often vomiting. The longer the operation, the more of the anesthetic enters the stomach, and the greater the liability to subsequent vomiting. At the termination of a prolonged operation upon an adult, if the patient's condition admits of it, and if the nature of the operation does not forbid it, I like to have a stomach-tube passed and the stomach well washed out with warm water. The washings smell strongly of the anesthetic, and the procedure greatly lessens the severity and frequency of postoperative vomiting (Geo. S. Brown, in "Surg., Gynec., and Obstet., August, 1905). After the administration of the anesthetic has been suspended and the operation has been completed the temperature is usually subnormal. The patient must be watched until consciousness returns. If he is left alone, a change of posture may lead to arrest of feeble respiration, the assumption of the erect position may cause fatal syncope, and mucus or vomited matter may block the air-passages and cause suffocation. The best position to place him in is the recumbent, the head being level with the body or somewhat lower and the side of the face resting on the pillow. Shock is treated by ordinary methods (see page 262). The inhalation of oxygen is of great value in rousing a patient from the state of anesthesia, and will often prevent vomiting. If vomiting occurs, the head should be upon its side or should be held over the edge of the bed, and after the spell of vomiting the mouth must be wiped clean. The face should be washed with cold water and be fanned rather actively. It is the routine practice of some surgeons to administer vinegar by inhalation during the reaction from an anesthetic. This proceeding sometimes seems to prevent vomiting. Some patients awake from anesthesia as from a quiet sleep; others are noisy, turbulent, and violent. The duration of the period of reaction varies with the anesthetic used, the amount given, and the personal tendencies of the patient. The patient must not be allowed to sit up for several hours at least. No food is to be allowed for at least six hours. Unless the operation was upon the stomach, I do not forbid water, but allow the patient to drink freely of hot water. This dilutes any irritant material in the stomach and dissolves mucus, and if vomiting does occur it serves to wash the stomach out. All fat patients, all patients with respiratory difficulties, or in whom we apprehend respiratory complications should, if there is no contra-indication, be placed in a sitting or, at least, a semi-erect posture as soon as reaction from anesthesia is obtained. If this plan is followed, ether-pneumonia and other respiratory troubles will very seldom develop.

After-effects of Anesthetics.—**Vomiting.**—I am convinced that in many cases postanesthetic vomiting is due or is largely due to irritation of the stomach caused by swallowing considerable quantities of an irritant anesthetic. The liability to it is greatly lessened by washing out the stomach before the patient leaves the operating table, and allowing the patient (in suitable cases) to drink freely of hot water as soon as he returns to consciousness. Most patients vomit more or less, but if the man has been drinking hot water an act of vomiting washes out his stomach and he may not vomit again. Violent vomiting may occur in spite of all our efforts, and may persist for hours, greatly exhausting the patient and doing infinite harm, it may be, especially if the operation were upon the brain or an intra-abdominal structure. If vomiting continues, forbid food absolutely. Very hot water in doses of a teaspoonful should be given at frequent intervals. Drafts of hot water may relieve the condition by washing out the mucus from the stomach. Other remedies which may succeed are: inhalations of vinegar, hot black coffee by the mouth, a mustard plaster over the stomach, fresh air in the room, small pieces of ice placed

in the mouth and sucked, small doses of iced champagne, and drop doses of a 3 per cent. solution of cocain or 3-drop doses of a 5 per cent. solution of eucain. The best remedy for persistent vomiting is lavage of the stomach. Some persons, as Dudley W. Buxton points out, suffer greatly from nausea, although there is little or no vomiting. In such cases Buxton uses 1 min. of tincture of nux vomica in a teaspoonful of hot water every ten minutes until six doses have been taken. If this plan fails, he gives drop doses of wine of ipecac or minim doses of dilute hydrocyanic acid.[1]

Vomiting from chloroform is usually more difficult to check than vomiting from ether. In any case of persistent vomiting examine for acidosis (see page 1207).

Backache.—This is a very common and often a very distressing consequence of anesthesia. It is complained of soon after consciousness is regained, it may persist for several days, and it is a not uncommon cause of wakefulness. It is usually greatly aggravated by turning and twisting, and by attempting to rise up from the bed. The pain is located in the lumbar and sacral regions and is often accompanied by rigidity of the lumbar muscles. Various explanations have been given of it. One view is that it is due to renal congestion. Another, that it results from congestion of the spinal cord. I believe that the explanation of most cases is that given by John Dunlop ("New York Med. Jour.," July 10, 1909), viz.: "The patient during the operation lay upon a flat table without support to the lumbar curve, consequently the sacro-iliac synchondroses were strained. The backache may be largely prevented by placing a small pillow so that it will support the lumbar curve during anesthesia."

Respiratory disorders are more often noted after ether than after chloroform. Bronchitis may follow or bronchopneumonia (*ether-pneumonia*). Respiratory difficulties may be due to chilling the patient by bringing him from a warm operating room through a cold hall and into a cool bedroom. Bronchopneumonia is especially common in septic patients, and may be due in some cases to septic emboli and in others to aspiration of septic material into the bronchi (cases of cancer of the tongue and pharynx, and cases with stercoraceous vomiting). They are treated by ordinary methods. If chloroform is given when a gas-light is in the room the vapor is decomposed and certain highly irritant products are formed, which, when inhaled, produce laryngeal spasm and possibly bronchitis. The irritant material is probably $COCl_3$. The treatment is to admit fresh air freely into the room, and to have the patient inhale vinegar and, later, oxygen. Ether-pneumonia must not be confounded with postoperative pneumonia, described by Wm. H. Bennett.[2] This latter condition may arise from seven to fourteen days after operation in robust, gouty people, and is usually unilateral. Some cases of respiratory disorder result from chilling while in the operating room, or while coming from it, rather than from the anesthetic. If the patient is placed in a sitting position or, at least, semi-erect in bed, as soon as he reacts from the anesthetic the danger of serious respiratory disorder will be at a minimum.

Renal Complications.—After the administration of an anesthetic, blood, albumin, sugar, acetone, or diacetic acid may appear in the urine, and the secretion may become scanty or even be suppressed. It is usually maintained that chloroform is less apt to irritate the kidney epithelium than ether, but there has been much dispute on this point. If casts and albumin are present before anesthetization, the condition may be rendered worse if ether or chloroform is given. If neither casts nor albumin are present, they will not be so apt to appear after taking chloroform as after taking ether, but if they do appear after chloroform, they remain longer than after ether (Legrain). The truth of

[1] "Anesthetics," by Dudley W. Buxton.
[2] "Practitioner," December, 1896.

the matter probably is, that if the kidneys are healthy a small or moderate amount of either drug is not particularly irritant; but if the kidneys are diseased, a small amount, and even if they are healthy, a large amount, of either drug produces decided renal irritation. Chloroform is less irritant because less chloroform than ether is given to secure and maintain anesthesia. Scantiness or suppression of urine may be due to operative shock rather than to ether or chloroform. If the urine becomes somewhat scanty or if albumin appears in it, give non-irritant diuretics, diaphoretics and cathartics, and employ proctoclysis. The treatment of acidosis is set forth below. If the urine becomes very scanty, use hypodermoclysis. If postoperative suppression arises, it is the usual custom to give intravenous infusion of hot saline fluid, but I am doubtful of its value. Exposure of each kidney in the loin and incision of its capsule to relieve tension is justifiable and may do good.

Acid Intoxication.—This condition has been called *delayed poisoning*, *acetonuria*, and *acidosis*. Diabetic coma is due to acid intoxication. It is known that even in healthy urine there may be a trace, but a bare trace, of acetone. A diabetic individual deprived absolutely of carbohydrates is apt to get acetone and diacetic acid in the urine. In such cases carbohydrates cause the prompt disappearance of the acetone and diacetic acid. In a case which shows acetonuria before operation Bonn gives glucose as a prophylactic ("Brit. Med. Jour.," Feb. 25, 1911). Even people who do not suffer from diabetes may develop acetonuria after anesthesia. In certain cases in which dangerous symptoms arise after anesthesia the urine shows increased acidity, may contain albumin or casts, and contains acetone bodies (particularly β-oxybutyric acid), diacetic acid, or both of these substances. The blood contains an excess of free fat and shows diminution of alkalinity. Acid intoxication is very much commoner after the administration of chloroform than of ether, but may follow the giving of any general anesthetic. It may occur in individuals whose tissues contain areas of fatty degeneration, but it also occurs in those entirely free from degeneration; in fact, children particularly suffer in this way after the use of chloroform. The actual operation has nothing to do with the trouble, and sepsis is not causative. The drug used as an anesthetic causes acute fatty degeneration of the liver and other organs, quantities of toxins are formed, and these toxins cause the symptoms. Diacetic acid and β-oxybutyric acid are by-products of the process and are antecedents or precursors of acetone. The symptoms arise after the patient has emerged from anesthesia and reacted from shock. There is persistent vomiting of thin and foul fluid, the patient is extremely restless and much excited, there may be delirium, but dulness and heaviness may take the place of restlessness and excitement and coma may arise (J. A. Kelly, in "Annals of Surg.," Feb., 1905). Usually the temperature is subnormal, but sometimes there is elevated temperature. In many cases jaundice arises. There is an odor of acetone on the breath. Latent cases free from symptoms usually get well. Slight cases and even some grave cases recover, but most of the grave cases die in from one to five days. A knowledge of this condition explains some otherwise inexplicable deaths, and also some cases of persistent postoperative vomiting and of retarded convalescence. In acid intoxication there is fatty degeneration of the kidneys, of the liver, of the suprarenal glands, and of the gastric mucosa. The occurrence of such a condition is an impressive admonition that a surgeon should operate quickly, that as little of the anesthetic should be given as possible, that the urine should be carefully examined each day after operation for certainly several days, and that chloroform should not be used for prolonged administration. The indication for treatment is to saturate the patient with alkalis. Sodium carbonate is usually selected. It may be given by the rectum, by the mouth, by hypodermoclysis, or intravenously. Rectal administration produces irritation and diarrhea. In acetonuria without clinical

symptoms alkalinize the urine by 4 or 5 dr. of sodium bicarbonate daily, given by the mouth. When the urine becomes alkaline it is to be kept so. When symptoms appear give from 10 to 20 teaspoonfuls a day by the mouth. If symptoms do not soon disappear give the drug intravenously. Severe acid intoxication is treated as follows: Encourage skin activity by wrapping the patient in blankets and surrounding him with hot-water bags. Give carbonate or bicarbonate of sodium intravenously. A solution of bicarbonate of a strength of from 3 to 5 per cent. is used. Labbé gives from 1 to 2 liters. If the patient improves, the sodium bicarbonate is again given by mouth. Some surgeons give citrate of sodium. Drennan gives a salt of calcium. Bevan and Farill ("Jour. Am. Med. Assoc.," Sept. 20, 1905) reported 1 case and collected 27 from literature. In this series there were 2 recoveries. (On this subject see Lewis Beesly, in "Brit. Med. Jour.," May 19, 1906; J. A. Kelly, in "Annals of Surgery," Feb., 1905; A. D. Bevan and H. B. Farill, in "Jour. Am. Med. Assoc.," Sept. 20, 1905; Geo. E. Brewer, in "Transactions Am. Surg. Assoc.," vol. xx, 1902; Labbé, in "Arch. gen. de med.," Dec., 1911, and in "Presse méd.," Feb. 5, 1910; Braun, in "Brit. Med. Jour.," Feb. 25, 1911.)

Postanesthetic Paralysis or Narcosis Palsy.—Paralysis may arise during anesthesia as a result of cerebral hemorrhage or embolism.

It sometimes happens that when a person has come out of the anesthetic sleep a palsy of some part is found to exist, the condition being peripheral and not central in origin. Peripheral narcosis palsies are pressure palsies, although it is held by some that the anesthetic has a toxic influence which distinctly lowers the capacity of the nerves to sustain pressure. Certain it is that palsy sometimes follows what seems a degree of pressure inadequate to cause such a result. Narcosis palsies may be due to pressure of an extremity upon a table edge or to pressure upon nerves by placing the patient in certain positions.[1] When the Trendelenburg position has been employed, the flexures of the knees are in contact with the edge of the table, and paralysis of one or both external popliteal nerves may be induced. When the patient lies upon the side any nerve of the arm or forearm may suffer, but the circumflex and radial are most liable to be damaged. When the arm is elevated to the side of the head, or when it is drawn out strongly from the body, the brachial plexus may be compressed by the head of the humerus (Braun, in "Deutsche Med. Woch.," 1894). When the arm is in external rotation and is drawn backward and outward the median nerve is stretched, and when the forearm is flexed and supinated the ulnar nerve is stretched (Braun, Ibid.). In most cases the paralysis involves muscles supplied by the brachial plexus and is due to drawing the arm upward and backward over the head, a position which may squeeze the cords of the plexus between the collar-bone and the first rib. Garrigues shows that the plexus is particularly apt to be squeezed when it is stretched by the head being drawn to the opposite side or being allowed to fall back.[2] According to Büdinger the mounting up of the clavicle squeezes the plexus as its cords cross the first rib. This surgeon thinks that extreme abduction of the arm may squeeze the cords.

Postanesthetic peripheral paralysis is most common in the arm, but may occur in the leg or face. The prognosis is good, as a rule. Slight cases are soon recovered from; more serious cases, in which degeneration occurs, may not be recovered from for months. The treatment is that of any pressure palsy.

Primary Anesthesia.—Instruct the patient to count aloud and hold one arm above his head. Give the ether rapidly. In a short time he becomes mixed in his count and his arm sways or drops to the side. There is now a period of insensibility to pain lasting only about half a minute, and

[1] H. J. Garrigues, in "Am. Jour. Med. Sciences," Jan., 1897.
[2] Ibid.

during this period a minor operation can be performed. The patient quickly reacts from primary anesthesia without vomiting (Packard).

Mixtures are used by some because of the belief that a mixture might eliminate some unpleasant feature or some danger from a particular anesthetic.

Mixture of Ether and Chloroform.—This may be used in varying proportions. Hewitt at times employs 2 parts of chloroform to 3 parts of ether.

Vienna mixture contains 1 part of chloroform and 3 parts of ether.

Mixture of Alcohol and Chloroform.—All the chloroform mixtures produce the effects of chloroform, but we are giving the drug in an unknown amount. It was believed by Sansom, who devised this mixture, that the alcohol prevents concentration of chloroform vapor by retarding evaporation. When used, 1 part of alcohol is added to 4 parts of chloroform.

Nitrous Oxid and Oxygen.—(See page 1211.)

A. C. E. Mixture.—This mixture was originally used by Harley in 1864. It is often valuable in cases in which ether cannot be given. It is composed of 1 part of alcohol, 2 parts of chloroform, and 3 parts of ether. Its action is supposed to be between that of chloroform and ether. The objection to the A. C. E. mixture, as to any mixture, is that the materials do not evaporate in the ratio in which they are mixed, hence an uncertain amount of chloroform vapor is being inhaled (Buxton). This mixture is given by some from a Junker and by others from an open inhaler. Plenty of air should be given with it. The anesthetic acts similarly to chloroform.

Billroth's mixture contains 1 part of alcohol, 3 parts of chloroform, and 1 part of ether.

Schleich's Mixture for General Anesthesia.—Schleich, in 1895, introduced *a new anesthetic agent* which he claims is safer than chloroform. This surgeon maintains that a material is safe as an anesthetic only when almost all of the amount taken in at an inspiration is expelled on expiration. The anesthetic is unsafe in direct proportion to the amount absorbed; and the lower the boiling-point of an anesthetic, the less is absorbed, hence an anesthetic agent, to be safe, should have a low boiling-point. Schleich makes three solutions. The first contains (by volume) $1\frac{1}{2}$ oz. of chloroform, $\frac{1}{2}$ oz. of petroleum ether, and 6 oz. of sulphuric ether. The second contains $1\frac{1}{2}$ oz. of chloroform, $\frac{1}{2}$ oz. of petroleum ether, and 5 oz. of sulphuric ether. The third contains 1 oz. of chloroform, $\frac{1}{2}$ oz. of petroleum ether, and $2\frac{2}{3}$ oz. of sulphuric ether. No. 1 is used for light anesthesia, No 2 for medium anesthesia, and No. 3 for deep anesthesia. The anesthetic can be given from an open inhaler or a towel. The anesthetic state is quiet, reaction is rapid, and vomiting occurs in but half the cases. The superiority of this new anesthetic has not been proved. It sometimes causes dangerous symptoms, and has produced death. Some surgeons, who formerly approved of it, have abandoned it. It will certainly not displace ether or chloroform. Schleich's mixtures are now seldom or never used in the United States. Petroleum ether has no anesthetic power, and Meltzer shows that it is dangerous and tends to paralyze the respiratory muscles. Willy Meyer ("Med. Record," August 15, 1908) believes in the Schleich principle, but substitutes ethyl chlorid with a boiling-point of 59° F. for the petroleum ether. He uses 17 per cent. volume of ethyl chlorid with 83 per cent. volume of the molecular mixture of ether and chloroform.

Ethyl bromid was first used by Nunneley, of Leeds, in 1849. It was reintroduced in 1882 and again in 1896. It is still sometimes used for short operations. It is given while the patient is recumbent. The unconsciousness is obtained in from one to three minutes and is rapidly recovered from, and there is no after-sickness. The unconsciousness lasts about three minutes. Three dr. are given to a child, and 6 dr. to an adult. A towel is put over the face and the entire amount is poured on at once, and as soon as the patient is uncon-

scious the towel is taken away and no more of the drug is given (Cumston). Even if consciousness is regained too quickly to suit the purposes of the surgeon, it is not safe to give more of the drug, a notable objection which chlorid of ethyl does not possess. Cases have been reported in which sudden death has followed the administration of this drug, and it should not be given if there is disease of the heart, lungs, or kidneys.[1] Twenty-four deaths from bromid of ethyl are on record (Guadiana). If it kills, it acts like chloroform. It may be given *before* ether to prevent unpleasant effects, but it is usually not considered proper to give before chloroform. Zematski, however, has used it before chloroform in 2000 cases ("Vratch," August 25, 1901). I know of 2 unpublished deaths from it in Philadelphia. I never use it and regard it as unsafe. The drug rapidly deteriorates, and the deteriorated drug is very dangerous.

Chlorid of ethyl is a rapid anesthetic and statistics imply that it is a safe one. My faith in it has been greatly shaken by knowledge of 3 unpublished deaths in Philadelphia. It was first used by Heyfelder in 1848. A committee of the British Medical Association condemned it in 1880. Carlson and Thiesing reintroduced it in 1895 (McCardie, in "Lancet," April 4, 1903). It may be sprayed upon a mask covered by six to eight layers of gauze, so that the drug will not evaporate too quickly in the air. Many anesthetists give it in a closed apparatus, the patient respiring into and from a rubber bag. I believe it should be mixed with air and that concentrated vapor is a danger to the heart. The odor of the drug is agreeable. From 5 to 10 gm. of ethyl chlorid are given for a short operation if the mask is used. The patient must always be recumbent when taking it. Early in the inspiration the pulse and respiration become rapid. When unconsciousness comes they should be normal. The anesthetic state is induced, when the mask is used, in from two to three minutes, and as soon as it is obtained the patient is allowed to get air. If the closed inhaler is used unconsciousness is obtained more rapidly. Excitement does not precede unconsciousness. The anesthetic condition lasts from one to three minutes, and it is recovered from rapidly, usually without vomiting or unpleasant after-effects. If the patient recovers too rapidly for the surgeon's purpose, more ethyl chlorid can be given. It is to be noted that complete muscular relaxation does not occur, in many cases the conjunctival reflex is not completely abolished, and often the pupils do not dilate. It has no superiority over nitrous oxid, except as to cost and portability, and sometimes it fails to produce complete unconsciousness. A large dose rapidly given is dangerous, as it may cause cessation of respiration and spasm of the diaphragm. A contraindication to its use is any respiratory obstruction. In many cases there is spasm of the masseters. Concentrated vapor administered for a considerable time lowers the blood-pressure, induces cyanosis and asphyxia, and would eventually cause death by respiratory failure (McCardie, Ibid.). Lotheisser, in a study of 2500 cases of anesthesia by this agent, reports 1 death. Ware collected 12,436 cases, with 1 death ("Jour. Am. Med. Assoc.," Nov. 8, 1902). Seitz, of Konstanz, collected 16,000 cases, with 1 death. Miller ("Jour. Am. Med. Assoc.," Nov. 23, 1912) estimates that there is 1 death in 13,365 administrations. It is perhaps safer than chloroform, not nearly so safe as nitrous oxid, and not so safe as ether. The drug is used for a brief operation or examination. It can be given to infants a few days old with reasonable safety, and it has been administered many times to the aged. When it kills, it acts in a similar manner to chloroform. I have often given it *before* ether to prevent unpleasant symptoms and to hasten the advent of anesthesia, but it must *never* be given before chloroform. Recently I have practically ceased to administer ethyl chlorid.

[1] See Cumston, in "Boston Med. and Surg. Jour.," Dec. 20, 1894.

Nitrous oxid gas may be used to obtain anesthesia for brief operations. It is contra-indicated when high blood-pressure indicates vascular degeneration, because apoplexy may follow its administration. It should never be given when the air-channel is narrowed, as in Ludwig's angina, abscess in or below the tongue, and thyroid enlargement (F. W. Hewitt, in "Lancet," July 20, 27, and August 10, 1907). This gas is stored in steel cylinders, in which it is liquefied. The gas is passed into a rubber bag (Fig. 795), and is given to the patient by means of a tube and a mouth-mask, a wedge being placed between the patient's molar teeth, and the nostrils being closed by the anesthetist's fingers. The wedge must be held by a string, so that it cannot be swallowed. The patient becomes unconscious in about one minute, and we know the patient is anesthetized by the stertor and cyanosis and the insensitiveness of the conjunctivæ. The pulse should be watched, and if it flags the administration must be suspended at once. The striking phenomena are asphyxial, stertorous respiration, cyanosis, and even convulsions, dilatation of the pupils, rapidity of the heart, and swelling of the tongue.[1] Muscular relaxation is not as complete as in ether-anesthesia. Slowing of the heart is a danger sign. If nitrous oxid causes death, it does so by asphyxia or by asphyxia and cardiac inhibition. A person rouses very rapidly when the administration of nitrous oxid is suspended. It is a useful plan to give nitrous oxid first and follow this with ether (see page 1214). By this method the patient is anesthetized rapidly and pleasantly with the nitrous oxid, and the anesthesia is maintained by the ether.

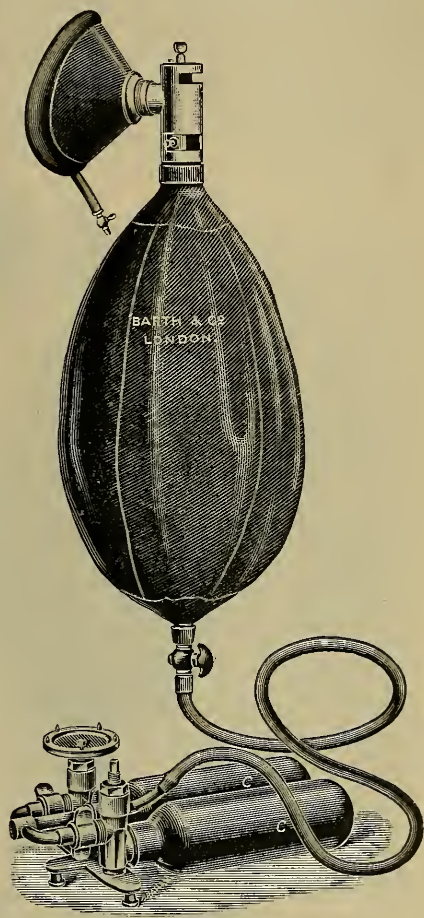

Fig. 795.—Hewitt's nitrous oxid apparatus.

It was formerly taught that nitrous oxid necessarily produces cyanosis, because the gas can only cause anesthesia by partially asphyxiating the patient. We know this is untrue, because if *nitrous oxid is mixed with oxygen* or atmospheric air anesthesia is obtained without cyanosis. Nitrous oxid is a genuine anesthetic agent. If a prolonged administration of nitrous oxid is desired, pure nitrous oxid can be given, a breath of fresh air being allowed, from time to time. By this method Preston has anesthetized many patients, the duration of the anesthesia being from ten to fifty minutes. A better plan is to give nitrous oxid and oxygen. I am satisfied that this combination does not occupy the place in surgery its merits entitle it to. One reason is the absolute necessity of having a specially skilled administrator. A trouble frequently encountered is persistent rigidity. This can often be prevented by a preliminary dose of morphin.

[1] See Hewitt, "Brit. Med. Jour.," Feb. 18, 1899.

Postanesthetic vomiting is rare (Teter, on "Thirteen Thousand Administrations of Nitrous Oxid with Oxygen," "Jour. Am. Med. Assoc.," August 7, 1909). Hewitt[1] formulates the following views as to the use of oxygen and nitrous oxid:

"In order to obtain the best form of anesthesia oxygen should be administered with nitrous oxid by means of a regulating apparatus (Fig. 796), the percentage of the former gas being progressively increased from 2 to 3 per cent. at the commencement of the administration to 7, 8, 9, or 10 per cent., according to the circumstances of the case. The longer the administration lasts, the greater may be the percentage of oxygen admitted.

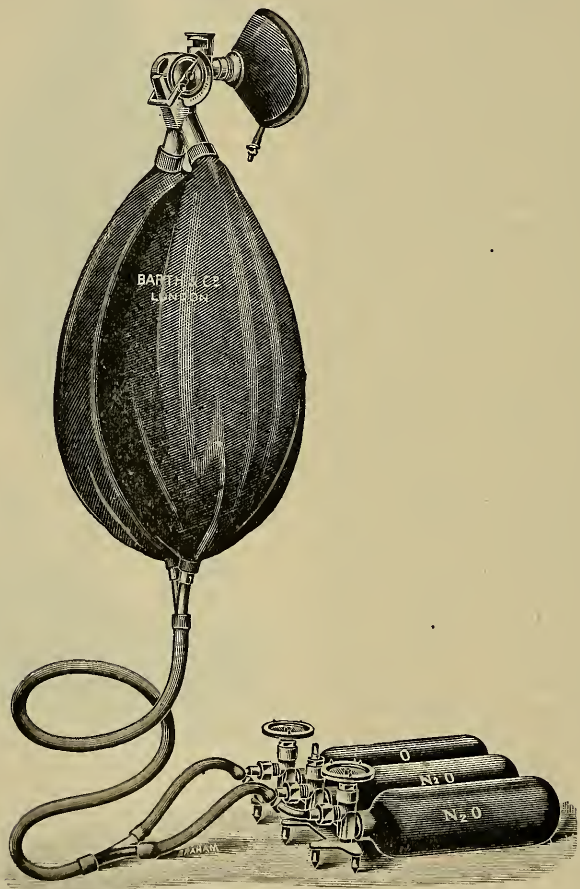

Fig. 796.—Hewitt's nitrous oxid and oxygen apparatus.

"The next best results to those obtainable by means of a regulating apparatus for nitrous oxid and oxygen are to be secured by administering certain constant mixtures of these two gases. Mixtures containing 5, 6, or 7 per cent. of oxygen are best for adult males, and mixtures containing 7, 8, or 9 per cent. are best for females and children. The next best results to those last mentioned are to be obtained by means of mixtures of nitrous oxid and air, from 14 to 18 per cent. of the latter being advisable in anesthetizing men and from 18 to 22 per cent. in anesthetizing women and children."

[1] "Brit. Med. Jour.," Feb. 18, 1899.

Crile uses nitrous oxid and oxygen as the anesthetic of choice for many operations, even major operations. He believes it produces less shock, less nausea, and less lowering of vital resistance to infection than does ether. He insists on the necessity of having a highly trained administrator and of keeping the patient *pink* during the administration. Respiratory failure is met at once by turning off the nitrous oxid and substituting pure oxygen. If relaxation is impossible (and it may be in a very muscular subject), ether is given until relaxation is attained and then a return is made to nitrous oxid ("Transactions of Southern Surg. and Gynec. Assoc.," 1909). Crile gives a small dose of morphia and scopolamin before operation to prevent too early postoperative appreciation of the "operative trauma."

The Gwathmey-Woolsey apparatus is a very useful one for nitrous oxid and oxygen administration (Fig. 797).

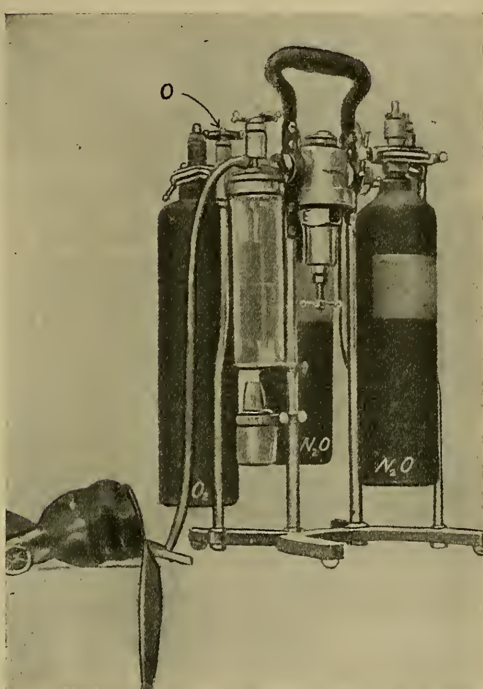

Fig. 797.—Gwathmey-Woolsey nitrous oxid oxygen apparatus with tanks in place: O, Regulating valve for oxygen; O_2, oxygen tank; N_2O, nitrous oxid tank.

Bichlorid of Methylene.—The composition of the so-called bichlorid of methylene is a matter of dispute. Some high authorities believe it to be a mixture of methyl alcohol and chloroform. It rapidly produces unconsciousness, and the patient returns quickly to consciousness when the administration is suspended. Some surgeons have thought highly of it, and claimed that it is pleasant, safe, and is not followed by vomiting as often as chloroform. The weight of opinion is that it is dangerous, death being similar to death from chloroform. It is given by means of a Junker apparatus.

Anesthetic Successions.—Bromid of Ethyl Followed by Chloroform or Ether.—(See page 1210.)

Chlorid of Ethyl Followed by Ether.—(See page 1210.)

Chloroform Followed by Ether.—Chloroform is sometimes given until the sensation becomes more or less obtunded, when ether is substituted. This is done to save the patient from the unpleasant sensations of etherization. It is a practice not to be commended, because it is precisely in the beginning that chloroformization is most dangerous.

Ether Followed by Chloroform.—When the patient cannot be relaxed or rendered unconscious by ether, or when some other complication develops, it is common practice to suspend ether and substitute chloroform. If the change is made, chloroform should be given cautiously. A large quantity should never be poured upon the inhaler at one time. The change should never be made when the patient is struggling, because the deep respirations which attend or follow struggling may lead to the rapid inhalation of a dangerous dose of chloroform vapor. Further, as Hewitt points out, when the patient is deeply under the influence of ether the change should not be made unless it is imperatively necessary.

Nitrous Oxid Gas Followed by Ether (Gas and Ether).—This very valuable method was suggested by Clover. I have used it repeatedly with great satisfaction. The patient is *made* unconscious by nitrous oxid and is *kept* unconscious by ether. Thus are avoided excitement, struggling, choking, and the very unpleasant sensations induced by ether. It lessens the amount of time requisite to obtain anesthesia and lessens the amount of ether used. More important even than this, the method is safe. It is more satisfactory in women and children than in men. In very muscular men and in very stout elderly men it should not be used. In many cases nitrous oxid causes a flow of mucus from the respiratory tract. Because of the frequency of this happening it is wise to precede gas and ether anesthesia twenty minutes by a hypodermatic injection of morphin and atropin (Van Kaathoven, in "Annals of Surgery," Sept., 1908), or of atropin alone. Many operators first anesthetize with nitrous oxid, using an ordinary dental apparatus, and then give ether on an ordinary inhaler. The anesthetist must bear in mind that ether must be given gradually, not suddenly, poured on in large amount. Others prefer to use a combined gas-and-ether inhaler. I use the Gwathmey-Woolsey apparatus (Fig. 797).

Hewitt ("Anesthetics and Their Administration") thus describes the administration by means of Clover's portable ether-inhaler fitted with a stop-cock and a detachable gas bag:

"If the patient be lying upon his back, his head should be turned to one side. The face-piece with the charged ether chamber is then applied during an expiration. Air will be breathed backward and forward. When the respiration is seen to be proceeding freely, and the face-piece fits well, the charged gas bag is attached to the ether chamber. Air will still be breathed, but not through the valves of the special stop-cock. When the valves are heard to be working properly 'gas' is turned on, and is likewise breathed through the valves. Three or four respirations (or about one-half of the contents of the bag) are allowed to escape. The valve action is now stopped by turning the tap at the upper part of the stop-cock. At the same moment at which the patient begins to breathe 'gas' backward and forward, the rotation of the ether chambers for the addition of ether vapor should be commenced. The administrator will, in fact, find that he can, in a few seconds from the commencement of the administration, rotate the ether chamber as far as '1' or '1½.' Should swallowing or coughing arise, he must rotate more slowly. Respiration soon becomes deep and regular, and more and more ether may be admitted. At about this juncture, if the apparatus has been fitting the face well, signs of nitrous oxid narcosis may appear, especially in those who are quickly affected by this gas. Should jerky breathing or 'jactitation' arise, one full inspiration of air may be admitted at the air-tap. It should be remembered, however, that in giving 'gas and ether' by this method, the object is to just steer clear of the clonus and 'stertor' of nitrous oxid narcosis and to gradually but increasingly mix ether with the gas.

"In muscular and vigorous subjects the quantity of gas above mentioned will be found to be, as a general rule, insufficient to lead to the usual signs of deep nitrous oxid anesthesia. The rotation of the ether chamber should be continued till the indicator points to '2', '3,' or 'F.'

"The mistake that is most commonly made is that of admitting air too soon. Should air be given during the first half or three-quarters of a minute, the patient will partially come round, hold his breath, set his teeth, and give a good deal of trouble. Duskiness of the features must be expected. Speaking generally, air should not be allowed until the patient is stertorous, when one breath may be given. In this manner the patient will continue breathing a mixture of nitrous oxid, ether, and air till the usual signs of deep ether-anesthesia appear,

when the gas bag may be detached, and the little bag ordinarily used with Clover's inhaler substituted."

Hewitt prefers to use a modified Clover inhaler, which permits of the introduction of ether after the inhalation of nitrous oxid has begun.

Hypnotic Anesthesia.—It is well known that Esdaile in India did numbers of operations upon patients in hypnotic anesthesia. Cloquet, as long ago as 1829, amputated a breast of a woman who was held free from pain by hypnosis. In 1851 Guérineau amputated the thigh of a hypnotized person and there was no sign of pain. But all subjects are not susceptible. Even susceptible subjects require to be hypnotized again and again for days before the operation. The method has its own dangers and has been entirely abandoned.

Scopolamin-morphin Anesthesia.—This method has been enthusiastically praised and I have used it with satisfaction in a number of cases, but I have grown afraid of it. In a patient in the Jefferson Hospital dangerous symptoms arose after a dose of $\frac{1}{100}$ gr. of scopolamin. Ely records a death from respiratory failure two hours after the administration of $\frac{1}{8}$ gr. of morphin and $\frac{1}{100}$ gr. of scopolamin ("New York Med. Jour.," Oct. 20, 1906). A number of deaths have been reported following its use and there are, beyond doubt, unreported cases. Four deaths in 2400 cases were certainly directly due to it (H. J. Whitacre, in "New York Med. Jour.," March 31, 1906). It has even been stated that the death-rate is 1 in 100 ("Semaine Medicale," Jan. 11, 1905). Scopolamin is chemically identical with hyoscin and must never be used unless fresh, as it decomposes in air and light. If given without morphin, it is inefficient. Large doses are certainly dangerous, and the combination should never be given in sufficient amount to induce anesthesia unaided. If used at all, it should only be as an aid to local anesthesia or to general anesthesia by ether or chloroform. I have used it as an aid to local anesthesia in 6 goiter operations and in 2 cases of removal of the Gasserian ganglion. It should not be used in heart disease (Hayem); in persons under sixteen or over sixty (Korff); in any one with a tendency to pulmonary edema or with any acute condition of the throat which interferes with respiration (A. C. Wood, in "American Medicine," Nov. 11, 1905).

It produces a drowsy, heavy state or actual sleep, and the patient can be kept unconscious with an extremely small quantity of ether or chloroform. For five or six hours after the operation the sleep continues, and in most cases there is no postoperative vomiting.

If it is used, a mixture is freshly made containing $\frac{1}{100}$ gr. of scopolamin and $\frac{1}{6}$ gr. of morphin, and this is given hypodermatically one-half an hour before the operation. During the operation the sleep may be maintained by small amounts of ether or chloroform. If symptoms of poisoning occur, artificial respiration and oxygen inhalations may be required, external heat is needed, and nitroglycerin, strychnin, or caffein should be given.

I agree with Kochmann that we are not as yet justified in recommending this method of anesthesia ("Münchener medizinische Wochenschrift," 1905, No. 17).

Local Anesthesia.—In every case requiring operation we should inquire whether local anesthesia should be used instead of general anesthesia. Many really extensive operations can be done under it, and its field has been greatly broadened by the knowledge that viscera innervated by purely visceral nerves are insensitive and sensation exists only in those which receive branches from the somatic nerves (K. G. Lennander, in "Mittheilungen aus dem Grenzgebeiten der Medicin und Chirurgie," 1902, Bd. x, Heft 1 and 2). Lennander shows that the parietal peritoneum is sensitive to pain, but not to touch—that the intestine, stomach, edge of the liver, mesentery, gall-bladder, urinary bladder, kidney parenchyma, lung, anterior wall of the trachea, tes-

ticle, and epididymis are insensitive, though the coverings of the testicle and epididymis are sensitive. My experience is that the viscera may be cut, sutured, and handled without any severe pain if they are not pulled upon. In removing an appendix the only pain felt will be when the meso-appendix is pulled upon or adhesions to the parietal peritoneum are separated. The advantages of operation under local anesthesia are freedom from the danger of anesthetic accidents, blood changes, and postanesthetic discomforts and dangers. The disadvantage is the knowledge of the patient as to what is taking place. He may become alarmed and turbulent, and may thus interfere with a necessary procedure at a vital moment. I have operated under infiltration anesthesia with satisfaction in the following cases: Gastrostomy, tracheotomy, rib resection, goiter, inguinal colostomy, typhoid perforation, abscess of the lung, gangrenous appendicitis, appendicitis in the interval, radical cure of hernia, strangulated hernia, suprapubic cystotomy, extirpation of the external carotid artery (Dawbarn's operation), amputation through the thigh, ligation of the thyroid arteries, varicocele, hydrocele, circumcision, and ligation of the femoral artery. There are many methods of local anesthesia.

Fig. 798.—Gebauer's ethyl-chlorid tube.

Freezing.—*Ice* and *salt* may be used. Take $\frac{1}{4}$ pound of ice, wrap it in a towel, and break it into fine bits; add $\frac{1}{8}$ pound of salt; then place the mixture in a gauze bag and lay it upon the part. The surface becomes pallid and numb, and in about fifteen minutes decidedly analgesic. A *spray of rhigolene* freezes a part in about ten seconds. It is highly inflammable. *Ether-spray* anesthesia was suggested by Benjamin Ward Richardson. *Chlorid of ethyl* comes in glass or metal tubes (Fig. 798). Remove the cap from the tip of the tube and hold the bulb in the palm: the warmth of the hand causes the fluid to spray out. Hold the tube some little distance from the part, and let the fine spray strike the surface. The skin blanches and whitens, and is ready for the operation in about thirty seconds. Freezing is only of value in a trivial operation and when only a single cut or stick is required.

Hypodermatic Injection of Cocain Hydrochlorate.—Cocain was discovered by Gaedeke in 1855. In 1884 Köller, of Vienna, demonstrated the value of cocain as an analgesic in ophthalmic practice. In 1885 J. Leonard Corning, of New York, showed that cocain when applied to a mixed nerve in man abolishes nerve conduction, as it was already known to do in the lower animals. In 1885 Halsted and Raymond induced anesthesia in the nerve distribution by injecting cocain about the inferior dental and lingual nerves (perineural injection). This was done before pulling a tooth. Schleich introduced infiltration anesthesia. Braun, Van Hook, and Matas did much to develop local anesthesia. A tremendous impetus was given to infiltration anesthesia by Harvey Cushing's report on herniotomy under local anesthesia ("Annals of Surgery," 1900, vol. xxxi). He used a very weak solution of cocain (1 : 1000). Cocain hydrochlorate is soluble in water, but should not be boiled in water. To boil it impairs its anesthetic power. A tablet of the drug should be sterilized by dry heat and dissolved in sterile water. Always bear in mind that cocain is sometimes a decidedly dangerous agent. There are a number of deaths from cocain on record. The urethra is a particularly dangerous region, and so is the face. It is undesirable to use more than $\frac{2}{3}$ gr. upon a mucous surface, and to inject

hypodermatically more than $\frac{1}{3}$ gr. The drug must never be injected into a vein. Moderately severe cases of cocain-poisoning are characterized by great tremor, restlessness, pallor, dry mouth, talkativeness, and weak pulse. In dangerous cases there is syncope or delirium. Death may arise from paralysis or from fixation of the respiratory muscles. Cases with a tendency to respiratory failure require the hypodermatic injection of strychnin. In cases with tetanic rigidity of muscles hypodermatic injections of nitroglycerin or inhalations of the nitrite of amyl should be given. In cases marked by delirium, if the circulation is good, hyoscin is given. In any case stimulants are given, a catheter is used, and diuresis encouraged. Cocain-poisoning is always followed by a wakeful night. Cocain should not be used in any considerable amount if the kidneys are inefficient. In using cocain try to prevent poisoning. Because of the dangers inherent in cocain, have the patient recumbent. One minute before giving the cocain administer hypodermatically 1 drop of a 1 per cent. solution of nitroglycerin and repeat the dose once during the operation. In operating on a finger, after making the part anemic, tie a tube around the root of the digit before injecting cocain, and after the operation gradually loosen the tube. A hot solution of cocain is more efficient than a cold solution, hence hot solutions can be used in much less strength and are safer. The method of injection is as follows: A sharp needle is held at an angle of 45 degrees to the surface and is pushed into the Malpighian layer. One or 2 min. of a 2 per cent. solution are forced into the Malpighian layer, and a whitened elevation forms. The needle is withdrawn, at the margin of the wheal is reinserted, and more fluid is introduced, and so on until the region to be operated upon has been injected. After waiting five minutes the operation is begun. If, after cutting the skin, it is necessary to cut the subcutaneous tissue, inject a few drops of a 1 per cent. solution into the tissue. After the completion of the operation, if a rubber band was used, it is loosened for a few seconds, tightened for a few minutes, again loosened and readjusted, and so on several times (Wyeth). In this way only a small quantity of cocain is admitted into the circulation at one time and toxic symptoms are prevented. For operations upon the eye a 1 to 4 per cent. solution is employed; 1 drop of fluid is instilled every ten minutes until 3 drops have been given. Rarely use over a 10 per cent. solution on mucous membrane, although in laryngeal operations a 20 per cent. solution may be required. For the nasal mucous membrane a bit of wool soaked in a 5 per cent. solution is inserted or a spray of 4 per cent. solution is thrown from an atomizer into the nostrils. In the rectum, vulva, vagina, and uterus use a 5 per cent. solution; in the urethra, a 4 per cent. solution, and in the bladder, a 2 per cent. solution.

Cocainization of a Nerve-trunk.—Krogius, Halsted, and Raymond pointed out that if cocain is injected into the tissue about a nerve-trunk (perineural injection), anesthesia will follow in the area supplied by the nerve. The anesthesia will be produced in five minutes, and will last fifteen minutes. If cocain is injected about the root of the finger, all of the tissues of the digit will become insensitive. Injection over both supra-orbital notches renders the middle of the forehead insensitive. Injection over the ulnar nerve causes complete anesthesia of its trajectory. This plan is extensively used in Helsingfors.

It has been demonstrated by Crile ("Jour. Am. Med. Assoc.," Feb. 22, 1902) that the injection of cocain into a nerve-trunk (endoneural injection) interposes an absolute block to the transmission of afferent and efferent impulses and greatly lessens operative shock. In 3 cases I employed this method to secure anesthesia for amputation of the leg. None of the patients felt pain and shock was trivial.

In two amputations of the entire upper extremity, although the patient was under ether, the brachial plexus was cocainized to minimize shock and

shock was very slight. The cocain was injected directly into the trunks (endoneural injection). The combination of local anesthesia and general anesthesia is part of Crile's **anoci=association operation,** a plan to rule out all noxious or noci influences ("Jour. Am. Med. Assoc., July 13, 1912). He points out that though a person under ether is without feeling, the greater part of the brain is still awake, nerve impulses still reach the brain and cause functional depression and morphological alterations in the brain cells (Crile's "Ether Day Address," 1910). He would prepare a patient by filling him with calm confidence, giving him morphin and scopolamin previous to operation, administering nitrous oxid, and isolating the brain from the field of operation by infiltrating the region with 1 : 400 solution of novocain. At the conclusion of the operation the region may be injected with the hydrochlorid of quinin and urea.

Eucain hydrochlorate (β-eucain) is far safer than cocain used in full doses, and in many cases is to be preferred to it. It is injected in the strength of from 2 to 5 per cent. It is soluble in water and can be boiled without destroying its properties, and hence can be readily rendered sterile. It occasionally, though rarely, happens that the injection of eucain causes sloughing, especially at the extremities, in fatty tissue, in tendon-sheaths, and in bursæ. It can be used on mucous membranes.

Stovain.—This agent is a local anesthetic introduced by Fourneau. It is as powerfully analgesic as cocain, is only one-third as toxic, and is slightly germicidal. It is dissolved in cold water or salt solution, and a solution used of the strength of 0.5 per cent. Adrenalin can be given with it. (See Sonnenburg, in "Deutsche medicinische Wochenschrift," March, 1905.)

Quinin-urea hydrochlorid in from $\frac{1}{4}$ to 1 per cent. solution causes prolonged local anesthesia. A solution of 1 per cent. is too strong—it causes the wound to heal slowly and produces induration. The drug has no toxic effect and can be used in considerable quantity; it lessens bleeding, and, by producing an effect for many hours, lessens postoperative pain. Quinin-urea hydrochlorid is used by infiltration (see below). It is dissolved in water or normal salt solution.

Novocain of a strength in solution of from 1 : 200 to 1 : 400 is preferred by some surgeons. It may be given alone or mixed with stovain. It is given by infiltration. The drug is soluble in water and the solution can be boiled without being impaired in anesthetic power. It is one-sixth as toxic as cocain.

Infiltration anesthesia is in most instances the preferred method of local anesthesia. It is a term used to indicate a form of local anesthesia in which the tissues are not only injected, but are distended decidedly with a fluid anesthetic indifferent in nature. It is called *terminal anesthesia* because the anesthetic acts upon the terminal branches of sensory nerves. It is called *regional anesthesia* because the fluid injected affects a particular part of a sensory nerve in its course. Infiltration anesthesia was devised by Schleich, of Leipsic, who was dissatisfied with cocain, because it is not safe and sometimes fails to produce complete local anesthesia, owing to want of thorough diffusion. He found that salt solution (0.2 per cent.), if injected into uninflamed parts, produced anesthesia. To obtain this anesthesia the part must be distended by wide infiltration. If minute quantities of cocain, morphin, and carbolic acid are added to the solution, the anesthesia becomes more thorough and more prolonged, and can be obtained even in inflamed areas. Schleich uses three solutions:

No. 1, a strong solution, which is used in inflamed areas: cocain hydrochlorate, 3 gr.; morphin hydrochlorate, $\frac{2}{5}$ gr.; sodium chlorid, 3 gr.; distilled sterile water, $3\frac{2}{5}$ oz.; phenol (5 per cent.), 2 drops.

No. 2, medium solution, which is employed in most cases: cocain hydrochlorate, $1\frac{1}{2}$ gr.; morphin hydrochlorate, $\frac{2}{5}$ gr.; sodium chlorid, 3 gr.; distilled sterile water, $3\frac{2}{5}$ oz.; phenol (5 per cent.), 2 drops.

No. 3 is the weak solution used to infiltrate extensive areas: cocain hydrochlorate, $\frac{1}{6}$ gr.; morphin hydrochlorate, $\frac{2}{5}$ gr.; sodium chlorid, 3 gr.; distilled sterile water, $3\frac{2}{5}$ oz.; phenol (5 per cent.), 2 drops.

The addition of adrenalin chlorid to the cocain solution is an advantage, as it retards the circulation and hence favors analgesia and lessens bleeding during the operation. A satisfactory fluid for infiltration is 1 part of a 1 : 1000 solution of adrenalin chlorid and 9 parts of a 0.5 per cent. solution of cocain (Gangitans, in "Riforma Medica," Sept. 9, 1903). Eucain and adrenalin are preferred by some. Barker uses distilled water, 100 gm.; pure sodium chlorid, 0.8 gm.; β-eucain, 0.2 gm.; chlorid of adrenalin, 0.001 gm. After injecting Barker's fluid the surgeon waits for twenty minutes before operating.

The injections are begun *in* the skin, not *under* it (Fig. 799), and are made one after another until the area to be operated upon is surrounded above, below, and on all sides with Schleich's solution. At each infiltrated area a wheal forms in the skin. This infiltration can be made painlessly by touching with pure carbolic acid the point where the needle is to be inserted, or by freezing this spot with ethyl chlorid. After infiltration of the skin with the cocain solution the surgeon waits for a minute or two and then operates; incision is made, and when deeper tissues are reached they are infiltrated before incising them. If a nerve comes in sight, touch it with a drop of pure carbolic acid. Van Hook says that the anesthesia obtained by this method is due to artificial

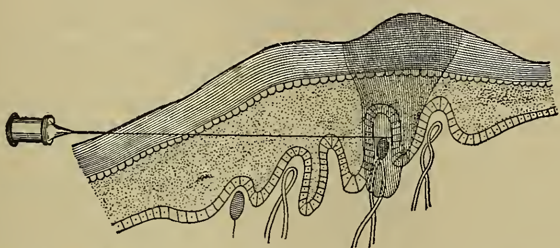

Fig. 799.—The syringe-point stops at the papillary layer, and the fluid lodges in the skin itself (Van Hook).

ischemia, pressure upon the tissues, the direct action of the drugs, and the lowered temperature.[1] The method is very efficient, and can be used for operations of considerable magnitude. Matas uses a special apparatus to infiltrate the tissues. The fluid is driven by compressed air, and widespread or *massive infiltration* is produced.

An ideal fluid to be injected should be isotonic with the blood, and should contain the smallest percentage of chemical agent necessary to render the part anesthetic. The solution recommended by Dr. James Mitchell, of Washington, D. C., seems to meet these requirements as closely as practically possible. Mitchell uses a tablet containing $\frac{3}{4}$ gr. of cocain and $\frac{1}{400}$ gr. of adrenalin. The tablets are dry sterilized, and just before operation are dropped into cups containing normal salt solution. Two strengths of solution are prepared: one tablet is dissolved in a cup containing 50 c.c. of the saline solution, one in a cup containing 100 c.c. The stronger solution is used for infiltrating the skin, blocking nerves, or for any particularly sensitive area; the weaker solution is employed for general infiltration of tissue. As Karl G. Lennander ("Local and Subarachnoid (Spinal) Anesthesia," in "Keen's Surgery," vol. v, page 1054) has pointed out, "Cocain has a greater affinity for the sensory than for the motor nerves. The effect of cocain in a certain proper concentration upon peripheral mixed nerves is to abolish, first,

[1] "Med. News," Nov. 16, 1895.

the sense of tickling, then the sense of temperature, thereafter the sense of pain, and, lastly, the sense of touch (pressure), and only thereafter the motor faculty, which may remain unaffected, although all the modalities of sensation have been paralyzed. During the retrogression of poisoning the faculty of motion is the first to return, then the sense of pressure, next the sense of pain, and lastly the sense of temperature." The addition of the adrenalin to the cocain solution is an advantage, in that it retards the circulation by contracting non-striped muscle-fibers in arteries and capillaries. The cocain is thus localized, its anesthetic action prolonged, and bleeding diminished during the operation. I do not believe that adrenalin in any way modifies the toxic action of cocain; indeed, Berry ("Am. Jour. Med. Sciences," Nov., 1905) seems to prove that it actually increases it. With the extremely weak solution recommended by Mitchell I have never seen the slightest physiological action of cocain. The total dosage of cocain given by infiltration should not exceed $1\frac{1}{2}$ gr. In 1 case I observed superficial sloughing of the skin when, by an operating-room error, three tablets had been dissolved in 50 c.c. of saline. I believe the slough was due to the high percentage of adrenalin.

The field of operative achievement under infiltration anesthesia has broadened to such an extent that it is difficult to definitely limit its possibilities when it is in the hands of one skilled in its use. It is necessary for the surgeon operating by this method to use an essentially different technic from that commonly employed in operations under a general anesthetic. He should be calm, equable, content to wait, and patient in spite of delay. He must be skilled in clean operative dissections, and accustomed to refrain from handling tissues unnecessarily. Failure is certain if the operator is not constantly engaged in this kind of work, for he must have learned, above all things, gentleness and willingness to spend plenty of time, and must have acquainted himself accurately with the sensibilities of the various tissues encountered in different operative fields. For the occasional operator to attempt major operations under infiltration anesthesia is to court failure. The patient should be informed that operation is to be a matter of intelligent co-operation, and in major operations it is wise to give a hypodermatic injection of morphin ($\frac{1}{4}$ gr.) a half-hour before beginning. This is usually sufficient to allay the apprehension natural in one about to undergo an operation. A tactful assistant should be detailed to sit by the patient's head and engage him in conversation, sponge his face, administer small sips of water, and, in other words, be what may be called the "psychic" anesthetist. The patient should not see any of the preoperative preparations; instruments should be carefully excluded from the range of his vision. Needless conversation and other noise should be avoided.

The special instruments required are: two Record syringes of 2 c.c. capacity and one of 5 c.c.; two fairly fine needles $1\frac{1}{2}$ inches in length and two coarser needles 2 inches in length; a pair of Mayo's $5\frac{1}{2}$-inch straight dissecting scissors with keen edges; dissecting forceps with teeth, and fine-pointed artery clamps. For example, let us take an appendectomy in a patient with a frank tuberculosis of the lung; a case in which general narcosis would cause damage and might prove fatal. The patient, having been prepared for operation (care having been taken to administer morphin a half-hour previously), is placed upon the operating table and made as comfortable as possible. The head is arranged upon a pillow, the arms are disposed comfortably at the sides, and a folded blanket is placed under the lumbar spine. The patient's wishes may be consulted as to whether he desires a piece of gauze placed over his eyes or not. Usually the patient, unless addressed, keeps his eyes closed. The psychic anesthetist engages the patient in conversation, the surgeon must show full confidence, be cheerful, and endeavor to communicate this frame of mind to his subject.

The easiest method of approach to the appendix under infiltration anesthe-

sia is McBurney's muscle-splitting incision. Begin infiltration by taking the 2 c.c syringe filled with the stronger cocain and adrenalin solution. Use a fine needle. Pinch up a small piece of skin, informing the patient that you are going to stick him slightly with a fine needle. Holding the needle almost parallel with the skin, barely insert the point under the epidermis and, at the same time, press on the piston of the syringe so as to obtain an infiltrated spot simultaneously with the introduction of the needle. The pain caused by the first introduction of the needle is trivial and even that degree is absent during subsequent insertions. A small wheal is produced, the integument assuming a blanched, pig-skin appearance. From the center of this infiltrated circle the needle may now be inserted painlessly to its full length *in* the skin (not *under* the skin), parallel with the surface. Do not insert the needle too deeply at this time. As the point of the needle travels the solution should be fed from the syringe. Ordinarily 2 c.c. of solution will infiltrate $1\frac{1}{2}$ to 2 inches of skin. After the superficial infiltration a coarser and longer needle should be used to infiltrate subcutaneous tissues. The incision may now be carried down to the aponeurosis of the external oblique. Infiltrate the muscular and aponeurotic portion of the external oblique. Make a split in the aponeurosis by a knife and continue by Mayo's scissors. Gentle clips with the scissors cause less pain than knife dissection. Retract carefully the aponeurotic layer. Infiltrate the internal oblique and split it. The transversalis and peritoneum are infiltrated with the stronger solution, which we employ at this point for the first time since the infiltration of the skin. These layers are then incised. Incisions in all layers of the abdominal wall must be of ample size to avoid unduly strong retraction. Up to this stage the patient should experience no pain unless one has thoughtlessly clamped a vein without previous infiltration with the stronger solution. The visceral peritoneum may be cut, clamped, burned, and stitched with impunity, but undue traction upon the mesentery immediately causes general cramp-like abdominal pain with consequent rigidity of the abdominal wall. The appendix, therefore, is sought for by gently following the anterior longitudinal band intra-abdominally rather than by attempting to pull the cecum out of the abdominal incision. Once the base of the appendix is found, the rest is easy. Traction on the meso-appendix must be gentle, and before tying it infiltrate it with the stronger solution. The crushing ligation and inversion of the appendix is not accompanied by pain. Occasionally the necessary traction on the mesocolon will cause the patient to have nausea, which is relieved as soon as the traction ceases. Suture of the abdominal wall now follows without special incident, except that very small gutta-percha tissue drains should be inserted just under the skin at one or both ends of the incision when infiltration anesthesia has been used. These drains take care of any possible oozing that may occur after the effect of the adrenalin has worn off.

By the use of infiltration anesthesia I have operated with satisfaction in the following cases: Tracheotomy, tuberculous glands of the neck, rib resection, goiter, drainage of a cerebral cyst, ligation of the thyroid arteries, gastrostomy, inguinal colostomy, typhoid perforation, abscess of the lung, chronic and acute appendicitis, appendiceal abscess, jejunostomy, radical cure of inguinal, femoral, and umbilical hernia, strangulated hernia, incisional hernia, resection of the bowel, suprapubic cystostomy, extirpation of the external carotid artery (Dawbarn's operation), ligation of the femoral artery, cholecystostomy, suture of fractured patella, amputation of the arm, amputation of the thigh, amputation of the leg, removal of stone from the pelvis of the kidney, posterior gastro-enterostomy, hysteropexy, kidney abscess, psoas abscess, and large numbers of minor conditions.

Patients after abdominal section under infiltration anesthesia very rarely

vomit at all, never have as much postoperative pain as those who were under a general anesthetic, and seldom have backache. Distention of the bowel is uncommon. The catheter is rarely required, and, of course, the blood changes, renal difficulties, and postoperative pneumonias are much less frequent than after general narcosis. Infiltration anesthesia cannot be ignored in such cases as diabetes, Addison's disease, sepsis, advanced Basedow's disease, diseases of the cardiac muscle, liver, both kidneys, etc. In children and high-strung individuals infiltration is usually impossible; in operations for extensive malignant growths, or during which complete muscular relaxation must be obtained, this form of anesthesia is absolutely contra-indicated.

To those interested in infiltration anesthesia I would suggest a careful study of Spalteholz's admirable illustrations of nerves (especially those of the extremities),[1] together with the perusal of the following writings:

H. Braun: "Die Lokalanästhesie, ihre wissenschaftlichen Grundlagen und praktische Anwendung," Leipzig, 1907. (A very full bibliography accompanies this excellent work.)

Harvey Cushing: "Observations Upon the Neural Anatomy of the Inguinal Region Relative to the Performance of Herniotomy Under Local Anesthesia," in "Annals of Surgery," 1900, vol. xxxi.

Theodor Kocher: "Text-Book of Operative Surgery," third English edition, by Harold J. Stiles and C. Balfour Paul, vol. i, page 16.

Karl G. Lennander: "Local and Subarachnoid (Spinal) Anesthesia," in "Keen's Surgery," vol. v, page 1045.

James F. Mitchell: "The Production of Local Anesthesia for Surgical Purposes," in "American Practice of Surgery," by Bryant and Buck, vol. iv, page 231.

Bier's Intravenous Method of Local Anesthesia.—This plan was described by Bier at the German Surgical Congress of 1908.[2] It permits of serious operations upon the limbs, operations for which ordinary methods of local anesthesia would prove quite inefficient. Suppose the surgeon intends to resect an elbow-joint: Mark the position of the veins on the asepticized extremity. Apply an Esmarch bandage from the tips of the fingers to well above the elbow-joint. This is the expulsion bandage. A thin soft-rubber band is applied around the arm above the Esmarch bandage, the bandage is removed, and a like band is applied below the elbow. The anesthetic is injected into a superficial vein of this bloodless area (the basilic or cephalic). The tissues above and about the vein are infiltrated. The vein is exposed, the syringe of the cannula is introduced, and ligatures are used as though we were going to give an ordinary intravenous injection of salt solution, except that the cannula is pointed to the periphery. The fluid used is a 0.25 or 0.5 per cent. solution of novocain. The syringe, containing 50 c.c. of fluid, forces the solution downward into the veins and the limb swells.

If the stronger solution is used, 50 c.c. are enough; if the weaker solution is used, 100 c.c. will be required. If resecting the knee, the injection should be made into the internal saphenous vein and twice the amount would be necessary as advised for the elbow.

After injecting the strong solution operation may be begun at once. After injecting the weak solution we should wait ten minutes. The bloodless area between the bands becomes anesthetic very promptly after the injection, the bones as well as the soft parts. The peripheral portion of the limb beyond the area between the bands becomes anesthetic after a short time and motor paralysis may follow. Such paralysis is eventually recovered from. If anesthesia between the bands is not attained within five minutes there has been some failure in technic (Bier, "Edinburgh Med. Jour.," 1910, v, No. 2). The

[1] "Hand Atlas of Human Anatomy," by Werner Spalteholz. Edited and translated by Lewellys F. Barker.

[2] Bier: "Ueber einen neuen Weg Lokalanästhesia au den Gliedmaassen zu erzeugen," "Arch. f. klin. Chir.," 1908, lxxxvi, No. 4.

analgesia is entirely satisfactory and passes away as soon as the band is removed. When the operation has been completed, wash out the vein with salt solution in order to prevent toxic effects.

By this method the anesthetic passes through the vein walls and becomes fixed in the tissues, and when the bands are removed it returns very gradually to the circulation, hence greatly larger doses may be given than should be admissible by any other method. Adrenalin should not be given with the novocain. Toxic symptoms are rare. The method is contra-indicated if there is arteriosclerosis. (See Carroll Smith, in "Jour. Am. Med. Assoc.," March 23, 1912; Page and McDonald, in "Lancet," Oct. 16, 1909; Hitzrot, in "Annals of Surgery," 1909, vol. i.)

Anesthesia by Infiltration with Sterile Water.—When the tissues are well infiltrated with warm or cold sterile water, anesthesia ensues promptly. I have not found it as complete as when cocain or eucain is employed, even when a considerable amount of fluid is introduced. Gant uses it in rectal operations and commends it strongly ("New York and Phila. Med. Jour.," Jan. 28, 1904).

Spinal Analgesia.—J. Leonard Corning in 1885 discovered that cocain injected between the spines of the eleventh and twelfth dorsal vertebræ produces analgesia of the lower limbs ("New York Med. Jour.," Oct. 31, 1885). From this observation spinal anesthesia springs. Bier produced complete anesthesia of the entire body except the head by the injection of a small amount of cocain into the subarachnoid space of the spinal cord. A solution of cocain of a strength of from 0.5 per cent. to 1 per cent. is used by some, but cocain cannot be boiled without impairment of its anesthetic power, and carbolic acid must be added to it in small amount. Hence cocain so prepared is not certainly sterile, and the carbolic acid added may induce harmful symptoms. (See Neugebauer, in "Wien. klin. Woch.," 1901, Nos. 50, 51, 52.) Some surgeons use a solution of eucain which can be boiled, but it is not so rapid and certain as cocain. Some use tropacocain (Illwicz). A solution of this drug can be boiled, is less poisonous than cocain, and somewhat slower in action. Experimenters tell us that $\frac{1}{2}$ to $1\frac{1}{2}$ gr. of cocain may be given, but it is not wise to give over 0.5 gr. I have used stovain in a number of cases. Some combine it with adrenalin, but the combination is not desirable in the subarachnoid space. The dose is 1 c.c. of a 5 per cent. solution. The analgesia lasts from one-half an hour to an hour or more, and was followed in my cases by retention of urine. Some have used novocain alone or combined with adrenalin.

A. W. Morton ("Jour. Am. Med. Assoc.," Nov. 8, 1902) takes chemically pure crystalline hydrochlorate of cocain, places it for fifteen minutes in a dry temperature of 300° F., and puts it in sterile tubes until wanted. The dose depends upon the locality in which he wishes to induce analgesia, and varies between 0.3 and 0.5 gr. The required dose is placed in the barrel of the sterile syringe and is dissolved in cerebrospinal fluid drawn into the syringe for that purpose. I now follow the plan of Mr. Arthur E. Barker. He believes that the specific gravity of the fluid containing the drug plays an important part in its localization within the canal ("Brit. Med. Jour.," March 16, 1912). He uses a fluid as nearly as possible isotonic with the blood. It consists by weight of 5 parts of stovain, 5 parts of glucose, and 90 parts of distilled water. Adrenalin is never added. It may do harm, it can do no good. This fluid seeks the lowest level it can find and mixes but little with the cerebrospinal fluid. The average dose is 1 c.c. of the 5 per cent. solution.

The syringe used is of glass and of a capacity of 2 c.c. The needle is the hollow one of Bier. The needle must be sharp, else it would not go through the dura. Barker's fine blunt cannula goes through the lumen of the needle.

The fluid to be injected is kept in sealed Jena glass ampoules, and should not

be more than a week or two old. The fluid is drawn into the syringe from the ampoule. The patient lies upon his side with the head and shoulders well raised and with the back curved. The back has been previously sterilized. The dressings are removed and the region to be punctured is resterilized. The spines of the third and fourth lumbar vertebræ are located, and the needle is entered in the midline beneath the spine of the third or fourth lumbar vertebra and is pointed upward and forward. The surgeon determines that he has punctured the subarachnoid space by lessened resistance and the appearance of fluid at the needle-opening. The injection is made slowly, the needle is withdrawn, and the puncture sealed by collodion. In performing the operation care must be taken to prevent the escape of the cerebrospinal fluid.

If the patient remains upon the side the nerve-roots of the dependent side are rendered analgesic some time before those of the uppermost side. If he is turned for a time upon the other side the nerve-roots of that side will quickly become anesthetized. To turn him upon the back will do the same thing, but less rapidly. If he is placed in a sitting position the rectum and anus are quickly rendered anesthetic.

The usual position for operation is on the back, but he may perhaps be upon his side. When the patient is placed upon his back promptly after injection the anal region becomes anesthetic in from one to two minutes, the lower extremities in from three to six minutes, and the upper extremities in from fifteen to thirty minutes. The anesthetic condition lasts from one to three hours or even longer, and is due to the contact of cocain with the nerve-roots (A. W. Morton, "Jour. Am. Med. Assoc.," Nov. 8, 1902).

After cocainization of the spinal cord surgical operations can be performed on many regions without causing pain. Among the operations which have been performed are resection of the knee, resection of the ankle, osteotomy, amputation of the leg, amputation of the thigh, hysterectomy, perforation of gastric ulcer, intestinal obstruction, strangulated hernia, excision of bowel, acute appendicitis, gastro-enterostomy, oöphorectomy, removal of ovarian cyst, and removal of rectum.

Spinal analgesia is not growing in popularity. It is regarded by most surgeons as a method to be used in exceptional cases. It should never be used as a routine procedure, and it will not displace ether or chloroform. By it analgesia can usually be secured. A. W. Morton (Ibid.) used it 673 times without a failure, and 60 of these operations were above the diaphragm. If we desire to obtain analgesia of the upper portion of the body the patient must be placed in the Trendelenburg position after the fluid has been injected. Most operators have had failures, especially above the diaphragm. In Sonnenburg's 1117 cases there were 78 utter failures ("Jour. de Chir.," Oct., 1908). Bier says that failures occur in 4 per cent. of cases; Moynihan says in 14 per cent.; Legueu says in one-seventh of the cases. In Barker's last 100 cases there were 3 failures. No one should attempt it who is not well trained in aseptic methods, because infection of the cord or its membranes will prove fatal. Untoward effects are common, and they may arise during or after the operation.

Sonnenburg had them in 193 out of 1117 cases. Among the untoward effects reported are grave collapse, temporary paralysis of the abducens nerve, of the facial nerve, of the hypoglossal nerve, meningitis, retention of urine, chills, elevation of temperature, incontinence of urine, persistent paraplegia, pain in the back and legs, perhaps lasting for weeks or even for months, nausea and vomiting during and after the operation, sweating, overaction of the heart, dimness of vision, cramps in the limbs, dyspnea, violent headache, involuntary evacuation of feces, and cardiac overaction. Many of the immediate symptoms are probably due to the absorption of the drug injected. The headache is due to tension and is relieved when some cerebrospinal fluid is with-

drawn by lumbar puncture. In 20 per cent. of Barker's cases ("Brit. Med. Jour.," March 16, 1912) there was more or less transient headache. In 16.3 per cent. there were nausea and vomiting.

Headache, vertigo, weakness, paresthesia, neuralgia may, in a few cases, persist for months or even years (Hohmeier and König, in "Archiv. für klin. Chir.," Oct. 8, 1910).

Whether or not permanent harm ever comes to the cord is not certain. Bristow ("Brooklyn Med. Jour.," 1902, xvi, page 410) reported the case of a man, fifty-five years of age, on whom he operated for hemorrhoids after spinal cocainization. An examination one month later indicated degeneration of the posterior and lateral columns of the cord (spastic lower extremities, ataxic gait, increased knee-jerk, ankle-clonus, and inability to retain urine). Marx ("New York Med. Record," Dec. 22, 1900) states that 1 case in his experience, after cocainization of the spinal cord, developed typical locomotor ataxia. Dandois ("Jour. de Chir. Brux.," April–May, 1901) reports a case upon which he had operated for traumatic rupture of the urethra. Spinal cocainization was employed. Paraplegia developed and lasted two months. Several cases of hemorrhage into the subarachnoid space are on record. Legueu states that persistent paraplegia and persistent incontinence of urine may arise ("Rev. de Chir.," Oct., 1908).

Is there any danger of death from spinal analgesia? If the operation is not performed with scrupulous aseptic care it is very dangerous. Even when performed by the best surgeons death may occur. Tuffier places the mortality at 3 in 2000, but excludes from consideration 3 deaths ("La Presse Médicale," vol. lv, 1901, page 190). Reclus finds 6 deaths in less than 2000 cases (Address before the Paris Academie de Médicine, March 19, 1901). Hahn, in 1708 cases collected from literature, found 8 deaths ("Mitt. a. d. Grenzgeb. d. Med. u. Chir.," 1900, iii, 337). The mortality is usually supposed to be about 3 in evey 1000 cases. Wm. N. Perkins ("New Orleans Med. Jour.," Jan.–Sept., 1902) collected 2345 cases with 16 deaths or 1 death in 146 administrations. Strauss's table shows 46 deaths in 22,717 cases (quoted by Hardonin in "Archiv. Générale de Chir.," August, 1908). In Barker's 2354 cases there were only 3 deaths "which could be in any way put down to the spinal method of anesthesia" ("Brit. Med. Jour.," March 16, 1912). Hohmeier and König ("Archiv. für klin. Chir.," Oct. 8, 1910) collected 2400 cases of spinal anesthesia: 12 deaths were due to it directly; 4 of them died of paralysis of respiration; 7 of the fatal cases were over seventy years of age. One victim was only thirty-two.

Cocain seems to act like a toxin on the pia and arachnoid. Examination of fluid withdrawn after the performance of cocainization shows that it contains polymorphic leukocytes (Ravant and Aubourg, in "Gaz. Hebd. de Méd. et de Chir.," June 27, 1901).

My belief is strong that the method should only be used for operations below the diaphragm, and I hold this belief in spite of the claim of Jonnesco that he operates with the aid of spinal anesthesia on any part of the body. It is most successful in operations below the umbilicus. I very seldom use it for operations above that level.

In a case in which, because of heart disease, pulmonary disease, kidney disease, or some other condition in which a general anesthetic is inadmissible, spinal cocainization is justifiable. It should be reserved exclusively for cases in which other forms of anesthesia are positively contra-indicated. The method should not be employed on those under fifteen years of age or on the subjects of central nervous disease. Barker disapproves of spinal anesthesia in "cases of extreme asthenia due to carcinoma, and of advanced toxemia depending upon septic peritonitis or obstruction, especially in later life" ("Brit. Med.

Jour.," March 16, 1912), although some surgeons regard such conditions as particularly demanding spinal in preference to general anesthesia.

A solution of Epsom salts has been used by Blake, Haubold, and Willy Meyer. It was discovered (Meltzer and Auer, "Am. Med.," Nov. 25, 1905) that subcutaneous injections of salts of magnesium produce local anesthesia. The same investigators later pointed out ("Med. Record," Dec. 16, 1905) that subarachnoid spinal injections of Epsom salts produce widespread and complete anesthesia. A 25 per cent. solution is used and 1 c.c. of this is given for every 25 pounds of body weight. After a wait of three or four hours the drug causes paralysis and analgesia of the legs and pelvic region. Sensation and motion do not return for from eight to fourteen hours. Retention of urine may last two days. The pulse and blood-pressure are unaffected, but the respiration is slowed. Large doses would endanger life by respiratory arrest. In view of the fact that in some cases the effect of the drug is inordinately prolonged, it is wise, when the operation is completed, to puncture the theca of the cord again and wash it out with salt solution. Guthrie and Ryan ("Amer. Jour. of Phys.," August 1, 1910) deny that magnesium salts have specific anesthetic properties and claim that anesthesia following their injection is due chiefly to asphyxia.

XXXI. DISEASES OF THE SKIN AND NAILS

Dermatitis venenata is a dermatitis resulting from irritants. It may be caused by wearing garments containing arsenic. A common cause is rhus-poisoning. Rhus-poisoning arises from the poison-oak, the poison-ash, the poison-ivy, and some other species of sumach. Actual touching of the plants is usually, but not always, necessary. Some suffer if they simply come near them. Some people are immune to rhus-poisoning, some are slightly susceptible, some are strongly predisposed. It is believed that toxicodendric acid is the irritant agent. The condition is most apt to arise when the skin is moist from perspiration.

The **symptoms** are burning, itching, redness, and edema of the affected parts. The hands and forearms are most apt to suffer, but any part may be attacked. If the penis and scrotum suffer from rhus-poisoning there is great swelling from edema. An eruption on the hands may inoculate the penis when that organ is handled. A vesicular eruption begins between the fingers. The eruption becomes violently inflammatory, and in the form of fierce red edematous inflammation spreads widely over the body. There may be slight fever. The condition usually begins to abate in two or three days and desquamation follows.

When one, knowing from experience that he is predisposed, feels the inaugural itching, he should at once apply to the parts a 1 per cent. solution of lactic acid in 95 per cent. alcohol (R. F. Ward, in "New York Med. Jour.," Dec. 26, 1908).

The **treatment**, when a moderate area is involved, comprises the application of cloths wet with a wash of lead-water and laudanum, or a saturated solution of acetate of aluminum (R. F. Ward, Ibid.). If an extensive area is involved, apply grindelia robusta (4 dr. to 1 pint of water) or moisten the surface frequently with sweet spirits of niter. Oxid of zinc ointment, containing 10 gr. of carbolic acid to 1 oz., gives great relief.

Furuncle (Boil).—(See page 137.)

Aleppo Boil (*Endemic Boil of the Tropics*, *Delhi Boil*, *Oriental Sore*, etc.).—Papules appear upon the exposed parts of the body. These papules, which ulcerate, do not cicatrize for at least a year, and leave ineradicable scars. The

condition is due to a protozoan. Man is infected by means of flies, lice, or other insects. The Aleppo boil was once apparently confined to India, Arabia, Persia, Egypt, Algeria, etc. Of late it is said to have appeared in Panama, the Philippine Islands, and Hawaii.

Erysipelas.—(See page 199.)

Erysipeloid.—(See page 198.)

Clavus, or Corn.—A corn is a tender painful, and circumscribed thickening of the epidermis, and is commonest over one of the joints of the toes. *Hard* corns are situated on exposed parts of the digits; *soft* corns appear between the digits, where the parts are kept constantly moist. Corns are caused by pressure.

Treatment.—The wearing of well-fitting boots will usually cause a corn upon the toe to disappear. Soak the feet often in water containing bicarbonate of sodium, dry them, and apply a circular corn-plaster to the corn to take off the pressure of the boot. Another method is to touch the corn with iodin every night and pare away the hard tissue every morning. An old and valuable plan is to paint the corn every night and morning with a mixture composed of salicylic acid, 40 gr.; extract of cannabis indica, 10 gr.; and collodion and flexible collodion, of each, 2 dr. After several days of the treatment soak the parts in hot water and scrape away the mass. *Soft* corns are treated by washing the feet often with ethereal soap, drying, gently removing the sodden epithelium, dusting the toes and between them with borated talc, and placing absorbent cotton between the digits. Incurable soft corns require the removal of the skin from the adjacent sides of the two toes and suturing the toes together (thus converting two toes into one). In inflamed corns employ rest and lead-water and laudanum, and let out pus when it forms. Remember that in old persons the cutting of a corn may cause senile gangrene. In the inflamed and painful feet of a person who has corns nothing gives so much relief as washing the feet with ethereal soap, soaking in hot water, and wrapping the feet for half an hour in cloths wet with a mixture composed of linseed oil and lime-water, each, 2 oz., and spirits of camphor, 1 dr.

Warts.—(See page 379.)

Onychia is inflammation of the matrix of the nail. Syphilis often causes severe onychia which requires specific treatment (see page 326). A *run-around*, or paronychia, is suppuration of the matrix at the root of the nail, and of the skin about it, of traumatic origin. It requires incision, trimming away of the buried edge of the nail, and packing with iodoform gauze (see page 724).

Malignant onychia, which is inflammation and ulceration of the entire matrix, occurs only in a person of dilapidated constitution. This condition requires removal of the entire nail, cauterization of the matrix, dressing with iodoform gauze, and the internal use of stimulants, tonics, and nourishing diet.

Ingrowing toe-nail (see page 157) is sometimes due to lateral hypertrophy of the edge of the nail, but usually to forcing of the soft tissues over the margin of the nail. An irritable ulcer arises. The condition is treated by splitting the nail, removing the ingrown piece, the soft tissue at the margin and the adjacent matrix, and dressing antiseptically.

XXXII. DISEASES AND INJURIES OF THE THYROID GLAND

The thyroid gland is an essential organ. It possesses functions of the first importance. It has a great influence upon nutrition. It acts by means of its secretion, which is an iodothyroglobulin.

An excess of this secretion if unneutralized in the body causes hyperthyroidism (see page 1236). A diminution of this secretion causes hypothyroidism

(see below). If there is no thyroid or a functionally inactive thyroid from birth, the child is a cretin (see below). A great deal of the gland can be parted with without harm. Charles H. Mayo estimates that one-sixth of the gland can furnish enough secretion for the body needs ("Illinois Med. Jour.," Feb., 1913). The older a person is, the less thyroid is apparently needed or, perhaps, the less thyroid, the older a person actually is. "According to Lorand, the deferring of old age requires the continued presence of some of the thyroid throughout life" (Charles H. Mayo, Ibid.). The thyroid of a woman is apt to enlarge at puberty and to become swollen from congestion before a period of menstruation. During pregnancy or at the menopause women are apt to exhibit symptoms of hypo- or hyperthyroidism. Charles H. Mayo (Ibid.) points out that increased secretion does not, of necessity, cause symptoms. A considerable excess may be neutralized in the body. In such a condition a shock may at once induce symptoms. Entire loss of the thyroid in an adult causes myxedema. Kocher pointed out that its complete removal in a young or middle-aged person usually causes *operative myxedema* (*cachexia strumipriva*) and perhaps *tetany*. Removal of the gland in an elderly person does not cause these curious conditions. Later knowledge indicates that removal of the thyroid with the parathyroids certainly produces myxedema or tetany, unless aberrant thyroids exist and compensate. Removal of the thyroid without the parathyroids does not induce tetany, even when there are no aberrant thyroids. The thyroid probably furnishes an internal secretion which destroys certain toxic products of metabolism. It is thought that the parathyroids furnish an antitoxin to poisons formed during digestion.

Wounds cause violent hemorrhage which is difficult to arrest. Ligatures may cut out and forceps will not hold. The hemorrhage is arrested by suture-ligatures, purse-string sutures, the actual cautery, or removal of the bulk of the gland.

The thyroid gland may be absent at birth. **Congenital atrophy** or **congenital hypertrophy** may exist.

Acquired atrophy leads to *hypothyroidism* and *myxedema*. Hypothyroidism may arise during any process destructive of the cellular activity of the thyroid gland. It is seen not unusually in women of from twenty-five to forty who have borne children. It sometimes occurs in men. The patient usually grows fat, is sterile, and neurasthenic. The temperature is subnormal. Complaint is made of headache, backache, shortness of breath, and indigestion. In women amenorrhea is the rule. In severe cases there is myxedema. (See Robert L. Pitfield, in "New York Med. Jour.," August 27, 1910.) *Myxedema* is a condition characterized by the presence of a firm subcutaneous swelling in the face, neck, and limbs; slow speech; mental dulness, and subnormal temperature. The condition is identical with that produced by removal of the entire gland.

Cretinism is a result of hypothyroidism. It is a form of infantilism and idiocy due to absence of the gland or atrophy of glandular elements in the thyroid. When atrophy of the parenchyma alone exists the size of the gland may be actually increased. The body is dwarfed; bone development is very defective, the face, neck, and extremities resemble those parts in myxedema, and a low grade of idiocy exists. Myxedema and cretinism are treated by the internal administration of thyroid extract.

Thyroid Feeding and Grafting.—Hypothyroidism, with or without myxedema, is greatly benefited by thyroid feeding or the administration of thyroid extract. Some experimenters have transplanted thyroids into thyroidectomized animals. The results show striking but temporary improvement. Such transplanted material eventually disappears. Experiments have been made and are being made on thyroid grafting in the treatment of cretinism and myxedema. Grafts have been placed under the skin, in bone at the junction of

the epiphysis with the diaphysis, in the spleen, and in other regions. Encouraging cases have been reported, but the results are temporary.

Congestion of the thyroid may be caused by violent exertion, prolonged effort, febrile maladies, and venous obstruction. It is treated by removing the cause and applying heat locally. Tracheotomy may be required.

Inflammation of the thyroid (*acute* or *inflammatory goiter*) may be induced by a septic or febrile malady, rheumatism, muscular strain causing vascular rupture, a wound, or contusion of the thyroid. Usually but one lobe is affected. The ordinary symptoms of inflammation are present. In addition there are dysphagia, dyspnea, venous congestion of the face, epistaxis, nausea and vomiting, and possibly delirium. It may terminate in resolution, suppuration, or fibrous induration.

Tuberculosis of the thyroid is usually a part of general miliary tuberculosis. It is very seldom that a local caseating focus occurs, but such cases have been reported.

Syphilis of the Thyroid.—Early in the secondary stage there is apt to be slight and painless thyroid enlargement. In the tertiary stage gummata may form.

Tumors of the thyroid are of various sorts. Among them are adenomata, cystic adenomata, sarcomata, and carcinomata. Eight cases of teratoma are on record (Isabella C. Herb, "Am. Jour. Med. Sciences," June, 1906). Malignant disease is unusual. I have operated on but 2 cases: 1 of cystic carcinoma in which operation was rapidly fatal, and 1 of round-celled sarcoma. The latter patient was living and apparently well four years after lobectomy. Malignant disease may arise in the normal, but is more apt to arise in a goitrous thyroid. In over 50 per cent. of the reported cases there is a history of antecedent goiter. Malignant disease is more common in women than in men and is very seldom met with before the age of thirty. It is most common between forty and sixty. One should always suspect malignant disease of the thyroid gland when the growth appears rather suddenly in a patient over forty years of age. If the growth is irregular in outline and is accompanied by pain and difficulty in swallowing, the diagnosis becomes reasonably certain. Later in the case there are symptoms due to pressure upon and infiltration of the nerves; the growth becomes firmly anchored and the lymph-glands adjacent to the thyroid become involved; there may be tracheal bleeding, and perhaps fever, and eventually cachexia develops. Sarcoma or carcinoma may occur and it is seldom possible to determine clinically with which we are dealing. The cancer may be a scirrhus or an epithelioma, but is usually an adenocarcinoma. A sarcoma may be either of the round cell or spindle cell type. In malignant disease of the thyroid, metastasis occurs early in a great majority of cases, the

Fig. 800.—Sarcoma of thyroid gland.

lungs being first involved, and then the bones and other structures; though it has been stated that in adenocarcinoma the lungs are likely to escape and that solitary bone-metastasis is not infrequently noted. Sarcoma (Fig. 800) may involve one lobe, but carcinoma (Fig. 801), even at an early stage, is apt to involve both lobes (Berry, "Diseases of the Thyroid Gland"). These growths soon penetrate the gland capsule, become anchored to surrounding parts, and involve the vocal cords, trachea, and even the great vessels of the neck. Malignant growths if not cystic are apt to be hard and nodular and they grow rapidly. At first the gland moves with deglutition, but later becomes anchored to surrounding parts. In malignant disease of the thyroid it is usual to find difficulty of swallowing and paralysis of the vocal cord on the side of the growth. Malignant disease is rapidly fatal. Many die within six months and few survive over eighteen months. Radical operation is proper only before the growth breaks through the capsule, although at any stage it may be necessary to operate in order to prevent suffocation.

Fig. 801.—Cystic-carcinoma of thyroid gland.

A **goiter**[1] is an enlargement of the thyroid gland not due to a malignant tumor or to inflammation. The enlargement may affect a small portion of the gland, one lobe, both lobes, or both lobes and the isthmus, and it may occur either sporadically or endemically.

There are a number of forms of ordinary goiter. The most common is what is called *simple* or *parenchymatous* goiter (Fig. 802). In this condition all portions of the gland enlarge, and the goiter is consequently bilateral. It does not appear first in one lobe and at a considerably later period in the other, but each lobe is enlarged equally or nearly equally. Parenchymatous goiter is often spoken of as simple goiter, and is sometimes, though not with entire accuracy, designated hypertrophy of the thyroid gland.

The common goiter of adolescence is "an edematous condition of the gland due to watery colloid" (C. H. Mayo, "Illinois Med. Jour.," Feb., 1913).

Adenomatous goiter (Fig. 803) is a condition due to the growth of encapsuled adenomata in the thyroid gland. There may be a single adenoma, but frequently there are multiple growths. One or both lobes may be involved. The goiter, however, usually seems to begin in one lobe; and if both lobes enlarge, one generally does so at a period distinctly subsequent to the enlargement of the other. In some cases growth seems to originate simultaneously in both lobes, but even then the growths seldom increase equally. Adenoma may develop in a healthy thyroid gland, but adenomatous growth is usually associated with some parenchymatous growth.

[1] For a study of the "Pathological Anatomy of Goiter" see W. C. MacCarty, in "New York State Jour. of Med.," Oct., 1912. This study is founded on 2500 cases from the Mayo Clinic.

Cystic goiter, or *bronchocele*, is a condition in which the chief mass of the enlargement is composed of a cyst or of multiple cysts. When cysts form, the thyroid gland is usually hypertrophied or adenomatous; occasionally, however, cysts form in a non-hypertrophied thyroid. The great majority of cysts are due to cystic degeneration of adenomata; some are formed by the running together of overdistended thyroid vesicles, and some few follow blood-extravasation into the thyroid tissue. The liquefaction is due to mucoid or colloid degeneration, and the fluid of the cyst is sometimes clear and thin, sometimes viscid, and often coffee-ground in appearance.

A *fibrous goiter* is a fibrous induration. It is likely to arise in old bronchoceles, which may actually pass into a calcareous condition. By the term *malignant goiter* is meant malignant disease of the thyroid gland, either carcinoma or sarcoma. As stated above, such cases are not really goiters. When hemorrhage takes place into a goiter the condition is often spoken of as a *hemorrhagic goiter*. A *colloid goiter* is a form of parenchymatous goiter in which there is an extremely large amount of colloid material. *Exophthalmic goiter* is

Fig. 802.—Parenchymatous goiter.

Fig. 803.—Adenomatous goiter.

discussed on page 1235. Occasionally a simple or an adenomatous goiter because of degenerative changes or overstimulation forms toxic material or an excess of secretion and causes symptoms of toxemia. "These cases may have all the nervous symptoms and heart complications of a bad case of Basedow's disease without the protruding eyes" (C. H. Mayo, "Illinois Med. Jour.," Feb., 1913). This evolution gives rise to what the French call a *Basedowified goiter* (Morestin, in "Rev. de Chir.," Nov. 10, 1899). A goiter that develops with great rapidity is sometimes called an *acute goiter*, and one that induces marked dyspnea is designated a *suffocating goiter*. Syphilitic, tuberculous, and amyloid enlargements are extremely rare, but occasionally occur. Further, a goiter may be back of the sternum, that is, *substernal* or *retrosternal*. A very movable goiter, which is now above and now below the sternal notch, is called a *wandering* or *diver goiter*. A goiter within the thorax is called *intrathoracic;* and such a goiter may be *retrosternal*, *retrotracheal*, or *retro-esophageal*. When a number of persons in the same region are attacked with goiter the condition is frequently referred to as *epidemic goiter*. When the condition is common in a certain district it is called *endemic goiter*. When a person living in a district in which the disease is rare develops goiter, we speak

of the condition as *sporadic goiter.* It has long been known that *accessory* or *aberrant thyroids* exist. The term "aberrant" is better than "accessory" because in some reported cases the thyroid proper was absent (V. L. Schrager, in "Surg., Gynec., and Obstet.," Oct., 1906). Aberrant thyroids are masses of tissue composed of structure identical with the thyroid gland, and distinct and separate from the thyroid gland proper. Median aberrant thyroids are found about the hyoid bone and are formed from remnants of the thyroglossal duct. Lateral aberrant thyroids are found and develop from the remains of the lateral anlages of the thyroid (Ibid.). Aberrant thyroids vary in number: there may be none, one, several, or chains of them. An aberrant thyroid may enlarge with the thyroid, may not enlarge even though the thyroid does, or may enlarge when the thyroid proper remains normal. When cachexia strumipriva does not develop after complete thyroidectomy, including the parathyroids, the patient has been saved by enlargement and functionation of accessory thyroids.

Causes of Goiter.—It is known that goiter is extremely common in the valleys at the foot of certain mountain ranges in Switzerland, southeastern France, northern Italy, the Austrian Tyrol, and in the Himalayas and the Andes. In a portion of England it is so common that it is referred to as the Derbyshire neck. It seems evident that the disease is due to the introduction of some poisonous element into the system; but what this element is, is not known. Some writers maintain that individual liability is developed by habits of life; others think that susceptibility depends upon hygienic surroundings; and some attach great importance to hereditary influence. The probability is, however, that the disease is due to the existence of some poisonous substance in the drinking-water. Some observers have blamed snow-water; many have laid the cause of the trouble at the door of water impregnated with salts of lime; but the real cause has not been demonstrated.

Some observers believe that simple goiter is due to bacteria in the intestinal canal, an important function of the gland being to save the body from poisons which reach the blood from the intestines, an excess of poison or certain powerful toxins causing the gland to enlarge.

An ordinary parenchymatous goiter seems to be a species of hypertrophy. A number of years ago I suggested the view that the gland has undergone such an enlargement and has become distended with colloid material because the human body has demanded more of the secretion of the gland than the normal gland has been able to supply; as a consequence, the normal gland has enlarged its capacity and increased its output.

Signs and Symptoms of Goiter.—One may determine that a growth is in the thyroid gland or is connected with it by studying a number of facts. A goiter, as a rule, follows the movements of the larynx and the trachea during deglutition, and this sign may be obtained in the great majority of instances. There are, however, rare conditions, such as hyoid cyst, in which a movement of the mass takes place during the act of swallowing, although the thyroid gland is not involved. Then, again, a malignant or an inflammatory growth of the thyroid usually becomes anchored to the surrounding tissues and does not show this mobility. Certainly, however, in the great number of cases an enlarged thyroid moves with the larynx and the trachea during swallowing.

Goiters vary greatly in size. Cases in which the goiter was as large as an adult's head, and some cases in which the goiter hung in front of the breastbone, and reached to below the level of the ensiform cartilage, have been described. A very large goiter may have a stalk.

When the entire gland, as well as the isthmus, is enlarged, or when the isthmus alone is involved, the swelling may appear to be in the median line of the neck. If the condition begins in one lobe, the growth will, for a time at least, be distinctly one sided; though when such a growth has attained a

large size, it may displace the windpipe and come itself to the middle line of the neck.

A goiter of any considerable size pushes the sternocleidomastoid muscle externally and anteriorly, and the muscles that run from the sternum to the hyoid bone and to the thyroid cartilage overlie the front of the growth. The carotid artery is displaced externally and posteriorly. The relation of the jugular vein to the carotid artery is usually profoundly altered. The artery, as already stated, goes externally and posteriorly, while the vein is actually pulled anteriorly and is flattened out upon the side or the anterior surface of the goiter; hence the vein comes to lie to the inner side of the artery. This curious alteration in relationship is due to the fact that the common carotid artery has no branches, and therefore is pushed externally with ease; but the internal jugular vein receives branches that lie in the tumor, pull upon the vein, and prevent its displacement with the artery (Lücke).

Berry alludes to the fact that the tumor, unless it is very small, usually reaches the upper level of the sternum, and frequently passes below this level; and that only extremely large goiters hang in front of the sternum, but that it is not at all unusual for prolongations from a goiter to extend for quite a distance into the mediastinum. A substernal goiter is productive of very dangerous symptoms and offers many difficulties in diagnosis. A goiter will occasionally wander, now appearing in the neck and again disappearing behind the sternum.

Some goiters are said to pulsate. This takes place in exophthalmic goiter, the vessels of the goiter pulsating as do the other vessels of the body; but in the ordinary simple goiter what is called pulsation of the goiter is usually the transmitted pulsation from the carotid artery.

Some of the most important symptoms of goiter are due to pressure and to the displacement of anatomical structures. Pressure upon the veins at the root of the neck causes great enlargement of the veins above the goiter and in it. Pressure upon the recurrent laryngeal nerve may induce characteristic symptoms (spasm of the glottis or paralysis of a vocal cord), but the dyspnea of goiter is due to pressure upon the trachea and not to interference with the recurrent laryngeal. Paralysis of a vocal cord is rare in non-malignant, common in malignant, goiter. Pressure upon the cervical sympathetic may cause contraction of the pupil and narrowing of the palpebral fissure (Berry). Pressure upon the cervical plexus or the brachial plexus causes paresthesia, anesthesia, or paralysis in the parts supplied by nerves from the compressed plexus. Pressure upon the larynx and the trachea may cause very great displacement, and any such displacement is productive of marked dyspnea. This displacement is usually to the side; and it may cause such a flattening out of the tracheal rings that when the tumor is removed the trachea collapses and the patient perishes of suffocation.

A parenchymatous goiter usually begins insidiously and grows slowly. It occasionally ceases to grow for a considerable period of time, and may even shrink. It frequently enlarges temporarily during menstruation or pregnancy, and occasionally attains an enormous size by changing into the cystic form. Alterations in its consistency and outline may be due to the developing of adenomatous masses.

In making a diagnosis between the different forms of goiter, one should remember that a fairly symmetrical, bilateral growth is probably parenchymatous; if it was symmetrical from the start the probability of its being parenchymatous is enhanced; that sudden enlargements are produced by hemorrhage; that cyst formation may lead to very great enlargement, and possibly to fluctuation; that if a non-malignant goiter induces dyspnea, it almost invariably does so by pressing upon the larynx and the trachea, whereas a malignant

goiter may do so by interfering with the nerves of the part or by infiltration of the trachea; that a non-malignant goiter very rarely produces difficulty in swallowing, but that a malignant goiter frequently does so; and that cough often exists if there is pressure upon the larynx or the trachea, such a cough being metallic in nature and unassociated with impairment of the voice.

In any goiter there may be cerebral symptoms, such as anemia, syncope, or even convulsions. Rapidly growing goiters are often fatal, and slowly growing goiters are very rarely so. A malignant goiter grows with great rapidity, becomes adherent, infiltrates, and quickly produces metastases, and both sarcoma and carcinoma produce metastases by way of the venous system.

Metastasis of Non-malignant Goiter.—An ordinary goiter which presents no sign of being malignant may suddenly be disseminated. The deposits are apt to take place in the bones and in the lungs. Tumors have been removed without any thought of thyroid trouble being responsible, and examination has shown thyroid structure. Patel collected 18 cases of thyroid metastasis ("Tumeurs bénignes du corps thyroide donnant des métastases," "Rev. de Chir." No. 29, 1904). The bones most apt to receive metastases are the bones of the cranium, the lower jaw, the vertebræ, the pelvis, and the long bones. In 4 of these 18 cases the spine was affected. Dercum has reported a case of thyroid metastasis to the spine ("Jour. of Nervous and Mental Dis.," Mar., 1906). Colloid goiters are particularly prone to metastasis. Some surgeons maintain that if a metastatic deposit grows and destroys bone, the primary tumor should be regarded as malignant, no matter what histological studies indicate.

Treatment of Goiter.—Iodid of potassium and arsenic internally have been advised. An ointment of red iodid of mercury[1] locally is advocated by some writers. It should be rubbed in while the goiter is exposed to the direct rays of the sun. The administration of thyroid extract may do much good in a case of parenchymatous goiter, but it is useless in other forms of the disease. It should be associated with the local use of tincture of iodin or ointment of red iodid of mercury. McCarrison ("Proceedings of the Royal Society of Medicine," Feb., 1912) grew cultures from the feces of individuals with goiter. He prepared a mixed vaccine. He also isolated certain bacteria and prepared vaccines from them. Cases of goiter were treated with the vaccines. It is claimed the vaccines, especially the mixed vaccine, will cure recent parenchymatous goiter. The vaccine is said to act more promptly than thyroid extract. In times past it was customary to treat cystic goiters by aspiration and injection with a solution of iodin. Electrolysis has been used for soft goiter, the negative pole being pushed into the growth, the positive pole being applied to its surface. In many cases the *x*-rays prove of benefit. In considering the propriety of operation remember that a goiter which begins at puberty may pass away. We should operate on every non-malignant goiter which is increasing in size steadily or rapidly. Operation is justifiable even if there is not pressure because the mortality is very small, and it saves the patient from the possibility of malignant change, of hemorrhage, and of inflammation. I always used to operate under local anesthesia. There is less bleeding under local anesthesia than under ether. It is a great advantage to have the patient conscious, because by asking him to speak during the operation the surgeon can tell if the recurrent laryngeal nerve is being approached or touched. Two cases of violent hemorrhage in conscious patients taught me a lesson. Each patient was conscious that something was wrong, became terrified and uncontrollable, and greatly increased the danger and difficulty. I now give ether (by intratracheal insufflation) unless there is very high blood-pressure, serious tracheal obstruction, or disease of the heart, lungs, or kidneys (C. H. Mayo, "Illinois Med. Jour.," Feb.,

[1] This ointment consists of 1 part of red iodid of mercury to 28 parts of vehicle (white wax and almond oil).

1913). When ether is to be given I precede its administration twenty or thirty minutes by $\frac{1}{6}$ gr. of morphin and $\frac{1}{120}$ gr. of atropin, given hypodermatically. In some cases I follow Charles H. Mayo's plan and combine local anesthesia with light general anesthesia. In some cases intraglandular *enucleation* is performed, in other cases *extirpation.* Occasionally these two methods are combined (Bergeat). Some surgeons advise simple division of the isthmus. Ligation of the thyroid arteries has been recommended. *Exothyropexy* is the operation of exposing the thyroid gland, dislocating it through the wound, and leaving it in this situation. Exothyropexy is now almost never performed, on account of the safety of the operation of thyroidectomy. Atrophy of the gland follows exothyropexy. Enucleation, if possible, is the desirable operation. It may easily be employed for the removal of a single adenomatous, colloidal, or cystic area. *Thyroidectomy* (extirpation) is employed when enucleation is impossible. The entire thyroid is not removed for an innocent growth: at least a portion of a lobe is left behind, otherwise operative myxedema will probably arise. Unilateral extirpation (*lobectomy*) is the method usually chosen. In cancer and in some cases of sarcoma complete extirpation may be attempted. The operation in malignant disease will occasionally prolong life, but it will rarely effect a cure. In malignant disease tracheotomy may be rendered necessary by urgent dyspnea. The operation is often very difficult because the growth may cover the trachea, the trachea may be deviated a considerable distance from its proper position, and the veins are very large. After the performance of the operation it is usually impossible to use an ordinary tracheotomy tube, and in such a case König's long, flexible tube (Fig. 804) is employed.

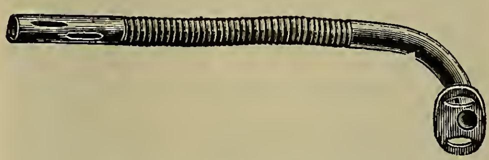

Fig. 804.—König's tracheotomy tube.

Endotracheal Goiter.—Such a goiter may be due to misplaced thyroid tissue, or may be a prolongation from the thyroid gland. Occasionally the growth is situated in front; but, as a rule, it is attached to the posterior surface of the larynx or trachea. The first symptom is dyspnea, which increases and becomes very severe. An examination with a laryngoscope makes the condition evident. Endotracheal goiter is much more common in the female than in the male. It is believed to begin usually at about the age of puberty, though it may exist for a long time unnoticed. In some reported cases the patients were forty years of age before being seen. The proper treatment for an endotracheal goiter is the performance of a preliminary tracheotomy and then extirpation.

Exophthalmic Goiter (*Graves's Disease; Basedow's disease; Pulsating Goiter*).—This condition was first described by Graves, of Dublin, in 1835. It is a condition of chronic overactivity of the gland (hyperthyroidism) in which the secreting structure of the gland is increased in amount. The increase of parenchyma may perhaps be general, may perhaps be in separated areas (C. H. Mayo, "Illinois Med. Jour.," Feb., 1913). The symptoms are very variable, depending upon the amount and nature of the thyroid secretion and also upon the nervous tendencies of the victim. It is vastly more common in women than in men, and is most common between the ages of twenty and forty. It may arise at puberty. It has been stated that child-bearing has little influence in its causation, but I have seen the development of it in a woman three times in three different pregnancies. There is no proof of heredity, but it is not unusual to find more than one member of a family with it. It is not particularly prone to appear in ordinary goitrous families, although a person with an ordinary goiter

sometimes develops all the nervous symptoms and heart symptoms of Graves's disease (see page 1231, Basedowified Goiter). It may arise after emotional excitement or depression, fright, shock, hemorrhage, or an acute illness. It may develop during the existence of locomotor ataxia, paresis, epilepsy, neurasthenia, hysteria and other nervous troubles, and abdominal and pelvic diseases. A shock or fright does not cause hypersecretion. That existed before, but there were no symptoms because the body was neutralizing the poison. Shock develops symptoms by abolishing neutralization (C. H. Mayo, "Illinois Med. Jour.," Feb., 1913). Crile ("Am. Jour. Med. Sci.," Jan., 1913) believes that "Graves's disease is not a disease of a single organ or the result of some fleeting cause," that it originates in fear, and is excited by "some stimulating emotion intensely or repeatedly given, or some lowering of the threshold of the nerve receptors, thus establishing a pathological interaction between the brain and thyroid." Digestive toxemia is thought by many to be the underlying cause. It is frequently associated with marked anemia the result of excessive vomiting. The disease is a toxemia and the real cause of the symptoms is hypertrophy of the thyroid and excessive secretion of the gland (*hyperthyroidism*). This view is rendered more probable when we recall that a condition known as myxedema possesses many symptoms directly opposite to those of Graves's disease and that myxedema is due to deterioration, great diminution or absence of thyroid secretion, and the unopposed action of adrenal secretion. The administration of thyroid extract to an individual may produce some symptoms observed in exophthalmic goiter and partial thyroidectomy may improve or cure Graves's disease. Iodothyroglobulin is, perhaps, the poisonous element.

Fig. 805.—Exophthalmic goiter and total blindness from protrusion of eyes (Hansell).

An apparent objection to this view is that Graves's disease may exist without detectable thyroid enlargement, but this objection loses force when we recall that the thyroid may be somewhat enlarged, though we cannot detect the increase. It is probable in exophthalmic goiter that whether or not there is an excess of thyroid products passing into the circulation, toxic materials of some sort are formed in the gland and are taken into the lymph and blood. The real cause of exophthalmic goiter is not positively proved, but it seems probable that the disease is due to the action on the sympathetic system of large amounts of thyroid material, of some poisonous product of thyroid activity, or of some toxin the thyroid fails to destroy.

In exophthalmic goiter the vessels of the gland are not dilated—in fact, they are "usually smaller and less numerous than in a parenchymatous goiter of the corresponding size" (Berry, on "Diseases of the Thyroid Gland"). The surface of the gland is smooth. On section, the cut surfaces seem solid and

very little colloid is visible. The enlargement is due to growth of the glandular epithelium, either general or in localized areas, and this epithelial proliferation may be induced by different exciting causes.

In exophthalmic goiter the lymphatics within the lobules are usually obliterated, but the lymphatics around the lobules are present in increased number and are of exaggerated size. Sometimes the thyroid becomes fibrous, and in such cases myxedema is apt to arise. In a typical case there are rapid pulse or *tachycardia*, protrusion of the eyeballs or *exophthalmus* (due to a collection of fat back of each eye), and enlargement of the thyroid gland or *goiter*. Either thyroid enlargement or exophthalmus may be absent—in fact, in some rare cases both are absent. The pulse-rate in most cases is from 90 to 140. Exophthalmus is present in at least 80 per cent. of cases. The enlargement of the thyroid is bilateral. Unilateral enlargements are instances of Basedowified goiter—that is, are cases in which toxemia arises in the course of an ordinary goiter (see page 1231). A systolic bruit is usually audible over the thyroid region, and the large vessels at the root of the neck pulsate strongly because of arterial dilatation. The cardiac symptoms are of great importance. Acute cardiac dilatation occurs during tachycardia, and for a time, at least, disappears as tachycardia abates. Even trivial fatigue brings on temporary dilatation. Dilatation may become permanent (and does after one year), valvular insufficiency may arise, or cardiac hypertrophy may occur (Grocco, in "Riv. Crit. di Clin. Med.," Jan. 2, 1904). *Von Graefe's sign* may be present; this is inability of the lids to follow the eyes in looking down. *Stellwag's sign* is retraction of the upper lids. The lids in some cases cannot be completely closed, and when the eyeball is suddenly turned up, the lid and brow may fail to act together. *Moebius's sign* is inability to maintain the eyes in convergence. In some cases ocular palsies exist, in others there is photophobia or nystagmus. Patients may suffer from neuralgia, colic, choreic movements, tremor, flushes of heat, and gastric crises. Tremor is practically always present when the arms and forearms are extended, the palms of the hands are turned down, and the fingers are spread apart. Widespread tremor is apt to arise from any excitement, shock, or surprise. Dyspnea often exists and albuminuria and polyuria are not uncommon. Hemoptysis, hematemesis, or mental disturbance is sometimes noted. The patient is usually greatly depressed mentally, sometimes is excited, and may have outbreaks of violent hysterical excitement or even of mania. The usual expression is one of fright. There may be insomnia, elevated temperature, excessive sweating, or sudden attacks of diarrhea. All symptoms are increased by fear or fright. Exophthalmic goiter is sometimes associated with osteomalacia. This fact is important in connection with MacCallum's observations on the action of the parathyroids in controlling calcium metabolism. Kocher emphasizes the importance of the blood-picture. In nearly all cases there is lymphocytosis. Halsted ("Annals of Surgery," August, 1913) says of his cases: "Almost invariably the proportion of lymphocytes was increased, once being as high as 65 per cent. But in 1 case, the most serious of all, the total percentage of lymphocytes was only 9." Halsted regards enlargement of the thymus as probably responsible for the lymphocytosis, and the thymus is enlarged in at least 75 per cent. of marked cases. After operation lymphocytosis gradually diminishes (Halsted, Ibid.). The duration of a case is entirely uncertain. It is usually very chronic, with remissions or actual intermissions. Sometimes the patient gets entirely well, but this result is rare. There is often a partial cure, which may at any time be followed by a renewed outbreak. Sometimes the condition passes away rapidly, but abatement is usually gradual. Some cases get progressively worse and die. Certain cases are acute and these are apt to result fatally. A man in the Jefferson Hospital died in five weeks after the first symptoms were noted. He was de-

lirious for several weeks. Another died in four weeks in spite of ligation of the two superior thyroids. Very grave cases of exophthalmic goiter are probably often associated with disease of the thymus (Rehn). C. H. Mayo ("Illinois Med. Jour.," Feb., 1913) says: "While the large majority of cases can be easily diagnosed from the nervous symptoms, tachycardia, goiter, and eye symptoms, there are a few cases in which it is difficult to diagnose true hyperthyroidism from pure neurasthenia, myocarditis, or Bright's disease, as well as a few cases in which there may be a complication by affection of the hypophysis, thymus, or adrenals."

Treatment.—Thyroid extract does harm. Medical treatment in a severe case should comprise rest in bed, the use of an ice-bag over the heart, and the administration of adrenalin. When the patient gets about again, he must avoid alcohol and all forms of excitement. Gentle exercise is desirable, but never violent exercise. Diet is to be nutritious, but non-stimulating. Electricity is said to be of benefit. Experiments in organotherapy are being tried in this disease. Thymus extract has been used. Ballet and Enriquez assumed that the thyroid gland furnishes an antitoxin to certain body poisons, that an excess of thyroid secretion over the amount required to neutralize toxin causes the condition known as Graves's disease, and that the symptoms of Graves's disease should disappear if sufficient toxin is administered to antidote the excess of thyroid secretion (Hubert Richardson, in "Am. Medicine," August, 1906). The two observers mentioned above obtained blood-serum from thyroidectomized dogs and injected it into individuals suffering from Graves's disease and claim that they noted improvement. In 2 of their patients, however, tetany developed. Lanz has used the milk of thyroidectomized goats instead of the serum of thyroidectomized dogs. The serum of thyroidectomized sheep, powder made from the dried goiter of a cretin, and the powdered flesh of thyroidectomized sheep have been used (Hubert Richardson, Ibid.). What is known as *thyroidectin* is the dried serum of an animal from which the thyroid gland has been removed. John W. Rogers and S. P. Beebe have made some extremely interesting studies on the production and application of a serum. Rogers makes two sera, using one or the other, according to the needs of the case. One serum, called the normal serum, is obtained from sheep or rabbits after injecting them with the combined nucleoproteins and thyroglobulin of healthy thyroids; the other, called the pathological serum, is obtained from the animals after injecting them with combined nucleoproteins and thyroglobulin obtained from the thyroids of Graves's disease. In 1 severe case I have seen rapid improvement and apparent cure follow the use of Rogers's serum. The value of serum treatment is as yet undetermined. It is certainly not free from danger and some deaths have followed its use One cause of diverse results after the use of goat serum may be found in the fact that some of the animals were probably incompletely thyroidectomized. The goat possesses aberrant thyroids and these must be removed as well as the gland proper.

There are upon the market three preparations to combat hyperthyroidism:

1. Thyroidectin (or thyreoidectin) is a powder made from the dried blood-serum of thyroidectomized animals. It is given in 5-gr. capsules. The dose is 1 or 2 capsules three times a day.

2. Beebe's serum is the serum of thyroidectomized animals.

3. The antithyroidin of Moebius is the serum of sheep's blood, the animal having had its thyroid gland removed at least six weeks before the serum was obtained.

Bilateral extirpation of the cervical ganglia of the sympathetic and division of each nerve below the ganglion has been employed, it is alleged, with benefit (Jaboulay). I have not employed the operation for this disease. Ligation of the thyroid arteries may do good. Its chief use is preliminary to thy-

roidectomy. Partial thyroidectomy is the operation commonly employed in severe cases; it cures within six months from 50 to 75 per cent. of the cases operated upon. One lobe, the isthmus, and a portion of the other lobe are removed. Some cases do not improve; others improve slowly and relief is only partial. It is the operation which I prefer. The Mayos have obtained a splendid series of results from this operation. It is their custom to apply the x-rays daily for several weeks and then to operate. The rays produce decided but temporary improvement. The operation is intracapsular extirpation of one lobe. Ether is given to most cases (by intratracheal insufflation). In some cases thyroid intoxication follows operation. In other cases very rapid growth follows incomplete removal, and the operation seems actually to have done harm. Sudden death occasionally follows the operation. The removal of an exophthalmic goiter is difficult; the capsule and blood-vessels rupture from slight force. All cases should not be operated upon. (See Operation for Exophthalmic Goiter on page 1243.) The x-rays frequently have a very beneficial effect upon the symptoms of exophthalmic goiter. They probably destroy some of the secreting glandular epithelium, and thus diminish the amount of the thyroid secretion and alter its character. They also induce fibroid changes, and 80 per cent. of cases are relieved. Frequently they cause great improvement, occasionally they will produce a cure. It is my custom to use the rays preliminary to operation in order to decrease the vascularity of the part, to lessen the amount and diminish the toxic quality of the thyroid secretion, and to modify the various symptoms.

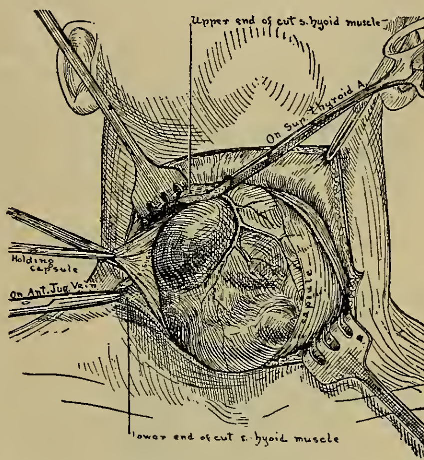

Fig. 806.—Enucleation of cystic goiter; capsule opened (C. H. Mayo).

Operations on the Thyroid Gland.—The removal of a goiter is a major operation and one beset with difficulties and dangers. Nevertheless it is a very successful operation. I lost a case of supposed adenomatous goiter which turned out to be a metastatic hypernephroma. The patient died from secondary hemorrhage. I lost a case of carcinoma of the thyroid and a case of simple adenoma. My mortality in ordinary goiter has been under 2 per cent. In 1200 cases of ordinary goiter the Mayos had a mortality of 1 per cent. following extirpation. Kocher's mortality is 0.4 per cent. Certain anatomical points are to be borne in mind. The internal jugular vein is frequently found to the inner side of the carotid artery and lying on the goiter (because the vein has branches which run to the goiter and hold the vessel against the thyroid). The recurrent laryngeal nerve ascends along the side of the trachea back of the gland, and is against the esophagus before it passes through the cricothyroid membrane. On the right side the nerve is very close to the inferior thyroid artery, sometimes passing over it, sometimes under it. On the left side it is deeper and not so near the artery. The parathyroids are behind the thyroid and usually behind the capsule.

In view of the fact that one or both recurrent laryngeal nerves may be paretic from pressure, all cases should be examined with the laryngeal mirror before the operation to determine this point. If the paresis is on one side only, the sound vocal cord may possibly compensate by advancing across the

midline. In such conditions the paresis may be first observed following operation, leading the operator to think that he has injured a nerve (C. H. Mayo, in "Surg., Gyn., and Obst.," July, 1907).

Intraglandular Enucleation (*Socin's Operation*).—By this operation an adenoma or cyst of the thyroid gland is removed, the encompassing glandular tissue being left in place. The capsule of such a growth is glandular tissue. The operation of enucleation is not suited to the removal of multiple tumors and it cannot be performed for parenchymatous goiter or exophthalmic goiter. Intraglandular enucleation is performed as follows: The thyroid is exposed by an oblique or by a transverse incision. An incision is made through the capsule of the thyroid gland and through the glandular tissue until the cyst or solid tumor is reached. As a rule, the tumor can be recognized by the fact that its color differs from the color of the thyroid tissue. The tumor is turned out by the fingers, a special scoop, the knife handle, or a dry dissector. In some cases a cyst can be most easily removed if, after exposure, it is incised and emptied and its wall is then grasped by strong forceps. A solid tumor should, if possible, be removed intact. The wound is packed temporarily with gauze, the edges of the cavity are grasped by forceps, the gauze is

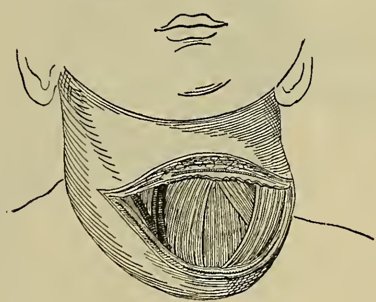

Fig. 807.—Kocher's transverse incision exposing the muscles and median veins of the neck (Kocher).

Fig. 808.—Isolating the accessory veins (Kocher).

removed, and every bleeding point is carefully ligated. The wound is closed by three layers of sutures—"one in the gland, one in the muscles, and a third in the skin" (James Berry, on "Diseases of the Thyroid Gland"). If the tumor is large, drain for twenty-four hours; otherwise, do not drain.

Enucleation is a very successful operation if performed upon properly selected cases, and can be performed rapidly, but the arrest of bleeding is often tedious and troublesome.

Extracapsular Extirpation.—This term means removal of the entire gland (*complete thyroidectomy*) or a portion of the gland (*partial thyroidectomy*) with the glandular capsule, the operation being an extracapsular procedure. Usually but one lobe is extirpated (*lobectomy*), or one lobe, the isthmus, and a portion of the other lobe. This method enables the operator to tie the chief vessels before he cuts them; as his vision is not obscured by bleeding, he can avoid cutting the glandular capsule (which would provoke copious bleeding), and he keeps a safe distance away from the recurrent laryngeal nerve.

If the patient suffers from grave respiratory trouble with myocardial disease, a general anesthetic is contra-indicated. If ether is used, after unconsciousness is obtained the ether is given by intratracheal insufflation. The patient

is placed recumbent, with the shoulders a little raised and the neck laid upon a sand-pillow so as to throw the head back as far as is consistent with comfortable respiration.

An oblique incision, a horseshoe-shaped incision, or a transverse collar incision (Fig. 807) may be made. I usually employ an incision shaped like an incomplete horseshoe, the convexity being downward. Layer by layer the tissues are divided. Vessels are carefully tied as divided or before division. The muscles which run from the sternum to the hyoid bone may in some cases be separated, but the extirpation of a large goiter requires transverse division

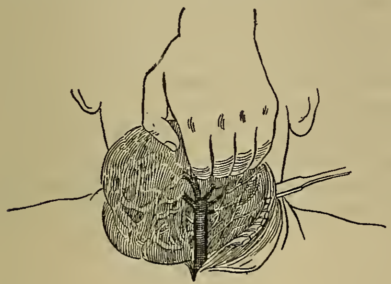

Fig. 809.—Exposure of veins at lower end before ligation (Kocher).

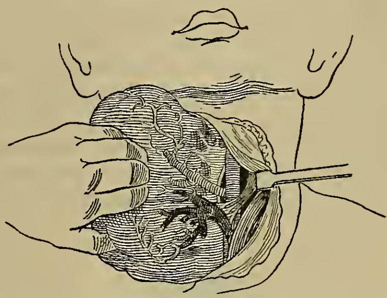

Fig. 810.—Dislocation of the goiter toward the right (Kocher).

of the muscles high up. The capsule of the lobe is exposed, and is separated from external parts (Figs. 808, 809, and 810). The upper portion of the gland is cleared. The superior thyroid vessels are found, tied with two ligatures each, and divided between the ligatures (Fig. 811). The clearing of the gland is carried on toward the median line and some rather large veins are encountered and tied (Fig. 813). The lower portion of the lobe is cleared and the inferior thyroid vessels are found. Near this point the recurrent laryngeal

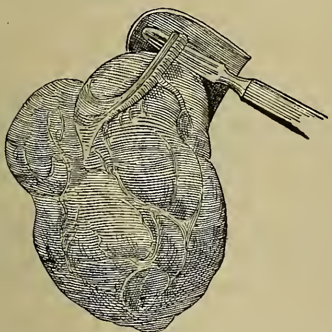

Fig. 811.—Isolation of the superior thyroid artery and vein (Kocher).

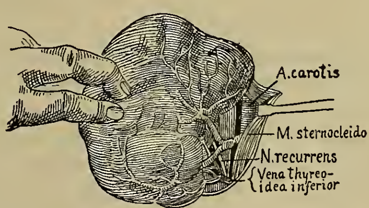

Fig. 812.—Ligation of the inferior thyroid artery (Kocher).

nerve lies and may be located. If the operation is being done under a local anesthetic adjacency to the nerve is readily determined, because if the nerve is pulled upon, or if it is pressed upon or touched by a blunt instrument, the patient's voice becomes metallic. A deliberate attempt is made to locate the nerve, and the patient is engaged in a conversation requiring answers while the surgeon is investigating. The lobe is lifted from its bed and dislocated from the wound and the inferior thyroid vessels are tied close to the border of the gland in order to avoid the recurrent laryngeal nerve (Fig. 812). The vessels are tied and

cut across as were the superior thyroid vessels. The isthmus is next exposed, clamped, ligated, and cut across, every care being taken to prevent colloid from being squeezed into the wound (Fig. 814). After dividing the isthmus, any bleeding point is ligated and the stump is cauterized. The divided muscles are sutured with catgut, a drainage-tube is inserted, and the superficial wound is closed with sutures of silkworm-gut.

Intracapsular Extirpation.—This operation is warmly advocated by the Mayos. The preservation of the posterior portion of the capsule protects the recurrent laryngeal nerve and greatly lessens the risk of injuring the parathyroids. Ether is given unless there is grave respiratory difficulty with myocardial degeneration, and half an hour before administering the ether the patient is given a hypodermatic injection of $\frac{1}{4}$ gr. of morphin and $\frac{1}{100}$ gr. of atropin. The ether is continued by intratracheal insufflation. When anesthetized, the patient is placed in the reversed Trendelenburg position and the shoulders are elevated (C. H. Mayo, in "Surg., Gyn., and Obst.," June, 1907). Kocher's transverse collar incision is made. Muscles are separated or divided as in ordinary extraglandular extirpation. If the ribbon muscles are divided the cut is made near their upper insertion to save their nerve supply and prevent the muscle scar from

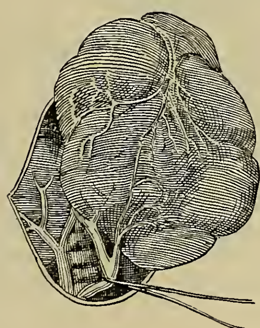

Fig. 813.—Isolation of the venæ thyreoideæ imæ (Kocher).

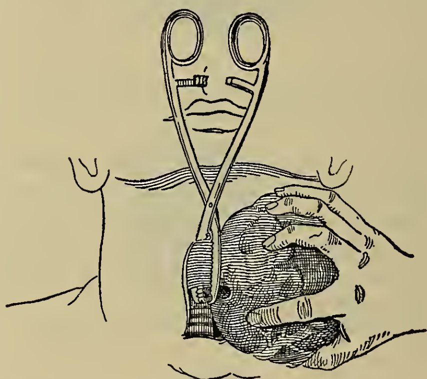

Fig. 814.—Isolation and clamping of the isthmus (Kocher).

being in line with the skin scar. The gland is elevated. The vessels entering and leaving the raised lobe are double clamped and tied. The capsule is incised along the outer side of the gland, is pushed back with gauze, and the lobe is drawn toward the midline, and vessels are caught by forceps, the tissues being grasped in line with the midline of the body (C. H. Mayo, Ibid.).

Every structure bearing any resemblance to a parathyroid is allowed to remain. The isthmus is clamped, divided, and closed by suture. The muscles and skin are sutured. Drainage is required after removal of large growths, a separate incision being made to permit of it.

Dangers in Goiter Operations.—During any operation for goiter sudden death may occur. In some cases a general anesthetic is responsible. In others suffocation arises from pressure upon or bending of the trachea or collapse of the trachea as the goiter is lifted from its bed. In rare cases dangerous dyspnea arises from irritation of the laryngeal nerves, and cardiac inhibition may be induced in the same manner. The parathyroids may be injured or removed and tetany may result. Rough handling and flooding the wound with colloid may be followed by great and even fatal hyperthyroidism. The trachea or esophagus may be opened. The recurrent laryngeal nerve may be injured. Air embolism seldom occurs. Reactionary or secondary hemorrhage is usually due to slipping of the ligature on the superior

thyroid artery "caused by including a piece of muscle" (C. H. Mayo, in "Surg., Gyn., and Obstet.," June, 1907).

Acute Thyroidism (Hyperthyroidism).—When colloid from the thyroid is squeezed into the wound during the operation or leaks into it later, it is absorbed and may produce serious symptoms or even death. This is most apt to happen in exophthalmic goiter. The symptoms always appear within forty-eight hours and usually within twenty-four. Sometimes they arise quickly after operation. In some cases in which this happens the patient never reacts from the operative shock, but develops a very rapid pulse and intense dyspnea, and dies in a few hours. In less severe cases there is a period of circulatory excitement, dyspnea, and elevated temperature (*thyroid fever*). The surgeon seeks to prevent acute thyroidism by limiting leaking of colloid, by cauterizing the stump, by washing the wound with adrenalin solution, suturing the capsule over the raw stump of the gland, and inserting drainage.

The Operation for Exophthalmic Goiter.—The operation of thyroidectomy is not to be performed during an acute exacerbation. To do it then will very probably cause death. Delirium is a contra-indication. So are gastric crises. The operation is very dangerous when there is great cardiac dilatation. After the disease has existed one year it is highly probable that marked dilatation exists.[1] Hence, early operations are much safer than late ones. If a case is seen early, and if the x-rays (and perhaps serums) fail to cure, operation should be recommended. In any case with serious symptoms the surgeon seeks to modify those symptoms before thyroidectomy by means of rest, the ice-bag over the heart, drugs, the x-rays, and perhaps serums. If under this treatment the dangerous symptoms disappear or greatly abate, thyroidectomy may be performed.

If the dangerous symptoms are little modified or not modified at all by medical treatment, preliminary ligation of one of the thyroid arteries is indicated. Ligation of an artery will not cure a case, but will probably greatly improve it. The operation is strictly palliative and preliminary. Tie the right superior thyroid. Wait one week. If the symptoms are not greatly improved, tie the left superior thyroid and wait a while. In severe cases tie both superior thyroids at one sitting. The operation is done under infiltration anesthesia. It is not entirely free from damage and may cause death. Halsted ("Annals of Surgery," August, 1913) ties one inferior thyroid or both inferior thyroids. He says that by the inferior operation we obtain a better cosmetic effect, leave a scar largely beyond the incision which will subsequently be used for lobectomy, and tie vessels which are larger than the superior arteries. In 1 of his cases four arteries were tied in 4 operations before lobectomy. C. H. Mayo[2] points out that the ligature of the superior thyroid should be applied very close to the pole or should actually include some of the thyroid tissue, "so that a reversed circulation in anastomotic branches with the inferior thyroid artery may not occur."

When it is esteemed safe the surgeon prepares to perform partial thyroidectomy. In most cases ether is given, preceded by a hypodermatic injection of morphin and atropin. After the patient is anesthetized by ether the tracheal tube should be introduced and the unconsciousness be maintained by insufflation anesthesia. If there is grave cardiac dilatation and we determine to operate, infiltration anesthesia is relied upon.

At the operation an entire lobe (except a thin slice), the isthmus, and a portion of the other lobe should be removed. The more of the gland removed, the better the prospect of cure (Halsted, "Annals of Surgery," August, 1913).

[1] C. H. Mayo, in "Collected Papers by the Staff of St. Mary's Hospital," Mayo Clinic, 1912; Halsted, "Annals of Surgery," August, 1913.

[2] "Collected Papers by the Staff of St. Mary's Hospital," Mayo Clinic, August, 1912.

At least one-half of one lobe must be left in order to prevent myxedema. The parathyroids are protected by leaving a small slice of the posterior portion of each lobe (Halsted, "Annals of Surg.," Aug., 1913). After the removal of one lobe the other usually undergoes considerable atrophy. After thyroidectomy, lymphocytosis gradually decreases, and an enlarged thymus generally disappears (Ibid.). Thyroidectomy may cure the case; it may greatly improve it; may fail or nearly fail, or may cause death. Cure is gradual and may be attained only after several months. From 50 to 75 per cent. of patients are cured by the operation. Many others are vastly and permanently improved. Some are improved, but are subject to temporary relapses. In Halsted's 39 cases there was not a death from operation.

In the first 16 cases operated upon by the Mayos the mortality was 25 per cent. At present the factors which forbid operation are recognized. In 1355 operations for exophthalmic goiter their mortality was under 4 per cent. They have had 278 consecutive cases without a death, a truly wonderful record.[1]

The elder Kocher ("Jour. Am. Med. Assoc.," April, 1910) reports upon 535 partial thyroidectomies for exophthalmic goiter. The mortality was 3.1 per cent: 3 died from the anesthetic, and now he uses local anesthesia preceded by Crile's plan of psychic narcosis; 3 others died from kidney disease which existed at the time of operation. Now he will not operate if kidney disease exists. There were 3 thymus deaths; 5 with status lymphaticus died suddenly while being prepared for operation. Such patients should not be operated upon unless they are greatly improved by medical treatment. Kocher, like Halsted, says that the degree of improvement depends upon the amount of gland removed. In such cases use medical treatment and the *x*-rays first. If this plan fails, tie one or more of the thyroid arteries before doing thyroidectomy.

My personal experience in exophthalmic goiter is small; in fact, I know of no one in Philadelphia who has performed any great number of operations for it. I have performed thyroidectomy for exophthalmic goiter 14 times, with 2 deaths.

The Parathyroid Glands and Tetany.—These glands were discovered by Sandström in 1880, and their vital functions were pointed out by Gley. He showed that removal of the parathyroids causes tetany.

The parathyroids are brownish red and are larger in adults than in infants. They are constant in man, never being congenitally absent.

They are usually four in number and are ordinarily placed external to the thyroid capsule. In some cases, however, one or more of them may be found embedded in the thyroid gland, but even when they appear to lie within the thyroid they are always separated from it by a capsule of connective tissue.

While there are usually four parathyroids, there may be only three, or there may be six, seven, or eight. Accessory parathyroids may be found over wide areas. One was discovered by Rogers and Ferguson in the middle of the posterior portion of the pharynx; and there was found in the thorax by Ogle a gland that was partly parathyroid.

From their situation the parathyroids are divided into superior, or external, and inferior, or internal. Walsh describes these glands in adults as being each from 6 to 7 mm. in length, 3 to 4 mm. in breadth, and $1\frac{1}{2}$ to 1 mm. in thickness. Each of these glands is supplied by a terminal artery, and the arterial supply is very largely obtained from the inferior thyroid artery or from the branch of anastomosis between the superior and inferior thyroid vessels.

If the parathyroid glands are extirpated from an animal, tetany usually develops (*experimental tetany*). This is positively the case in dogs. These glands certainly have most important functions in the metabolism of the body.

[1] C. H. Mayo, in "Collected Papers by the Staff of St. Mary's Hospital," Mayo Clinic, 1912.

They are essential for normal metabolism (Mayo and McGrath, in "Annals of Surgery," Feb., 1912). MacCallum and Voegtlin ("Johns Hopkins Hosp. Bull.," March, 1908) believe that damage or removal of them causes great changes in calcium metabolism.

Very little is known of diseases of the parathyroid glands. A few cases of tumor have been reported, each being an example of either work-hypertrophy or adenoma. One of these cases was reported by the author in "Surg., Gyn., and Obst.," Jan., 1909. In this case the tumor was removed under the impression that it was an adenoma of the right lobe of the thyroid gland. The pathological report, however, showed it to be a parathyroid. No trouble of any kind followed the operation, though at a later period enlargement of the opposite side of the neck occurred. This has been let alone through fear that it may be a left parathyroid. In spontaneous tetany histological changes have been found in the parathyroids and there is some evidence that traumatism may produce functional insufficiency.

Some persons have maintained that deficiency of parathyroid secretion is the cause of paralysis agitans, but this idea has been warmly combated and lacks evidence. Some observers believe that there is a deficiency of parathyroid secretion in exophthalmic goiter.

In view of the well-known fact that removal of or damage to the parathyroids may result in tetany (*hypoparathyroidism*), provided that several of these glands or all of them are damaged or removed, it becomes the duty of the surgeon, when operating for goiter, to exercise the utmost care that he does not remove any of these bodies. The safest way to avoid them is to retain the posterior portion of the capsule of the thyroid gland. If, during an operation, any small body that resembles a parathyroid is detected, it should be let alone; or if such a body has been accidentally removed, it should immediately be implanted into the capsule of the lobe of the thyroid gland that has been left undisturbed. It is highly improbable that the removal of even both parathyroids on one side will cause tetany if there are two normal parathyroids on the opposite side.

On account of the possibility of the development of tetany the question of the transplantation of parathyroids from animals becomes extremely important. Halsted has made some very valuable experiments upon the auto- and isotransplantation of the parathyroid glands in dogs ("Annals of Surgery," Oct., 1907; "Jour. of Experimental Med.," vol. xi, No. 1, 1909). He has shown that if the parathyroid be transplanted into an animal with normal parathyroids failure will follow, and the transplanted glandule will disappear. If, however, there is parathyroid deficiency in the animal into which the transplantation is made, the glandule will attach itself and grow. He obtained the best results by placing the parathyroid beneath the posterior sheath of the rectus muscle of the abdomen. Some observers have placed it in the spleen; others, within the peritoneum and in various other regions.

One of the dogs experimented upon by Halsted and reported upon in "Jour. of Exper. Med.," vol. xi, No. 1; 1909, lived in perfect health "for fifteen months and was in good health until the performance of the final operation, at which a parathyroid autograft" was removed. The dog died in three months from hypoparathyroidism (Ibid., No. 3, 1912).

If tetany follows thyroidectomy, it may be treated by the intravenous, rectal, or stomach administration of a 5 per cent. solution of lactate of calcium (MacCallum and Voegtlin, Loc. cit.). Beebe and Berkeley have prepared a parathyroid serum which they claim is efficient. Charles H. Mayo maintains that in tetany either the serum or the calcium lactate should be used, in the hope of tiding the patient over until parathyroid glands can be secured and implanted ("Annals of Surgery," July, 1909). The calcium salt may be given

intravenously, subcutaneously, by the stomach, or by the rectum. Joseph H. Branham ("Annals of Surg.," August, 1908) has reported tetany following thyroidectomy cured by the subcutaneous injection of parathyroid emulsion. The emulsion was made by grinding up fresh glands of beeves in a mortar, and then pouring 400 c.c. of sterile salt solution into the mortar. The preparation was filtered through sterile gauze and was administered beneath the patient's breast.

When tetany begins to develop in a patient there are usually headache, dizziness, and pain in the extremities. The muscles in one or both forearms and hands are liable to be affected. The hand flexes at the wrist, while the fingers are extended, and in some cases the forearm flexes at the elbow. Now and then the fingers will flex at the metacarpophalangeal joints, but the distal phalanges will remain extended. These spasms are painful. Similar spasms may occur in the feet and toes. In most severe cases the trunk muscles and those of the chest, throat, and eye may be involved.

Trousseau, years ago, showed that a spasm may be brought on in the affected limb by pressing upon the nerve-trunks and blood-vessels; this is called the *Trousseau sign.* Pressure upon the facial nerve may induce the spasms, and it is called *Chvostek's sign. Erb's sign* is a great increase in the galvanic irritability of the motor nerves. *Hoffmann's sign* is excessives sensitiveness of the sensory nerves. *Schultze's tongue sign* ("Münch. med. Woch.," Oct. 31, 1911) is said to be invariably present in adults with tetany. If the side of the tongue is tapped the organ responds by grooving itself on that side. If the tongue is lifted by a spatula and the dorsum is tapped a constriction like a waist forms.

Tetany due to absence of the parathyroids will inevitably prove fatal if not treated actively.

Before we understood the necessity of guarding the parathyroids tetany after goiter operations was not uncommon. The preservation of the posterior portion of the capsule has almost abolished this peril. In 3203 operations on the thyroid performed at the Mayo Clinic in St. Mary's Hospital, Rochester (up to Dec. 1, 1911), there was but 1 case of tetany and the symptoms in that were slight and transitory.

XXXIII. THE CAROTID GLAND; THE THYMUS GLAND

The Carotid Body or Gland.—This structure was discovered by Haller in 1743. It has no known function. It is about the size of a grain of rice and lies in or very near the carotid bifurcation, being adherent usually to the common carotid, occasionally to the external carotid. Tumors may form in this little body. The type found is the perithelioma. Such a tumor grows slowly, is hard, is movable from side to side, but not up and down, and is lifted with each beat of the carotid artery. In the long run it tends to become malignant. As the tumor grows it comes to surround the common carotid artery.

Treatment.—Operation on an advanced case is very difficult, will probably require ligation of the common carotid, and cause grave injury to important nerves. In one of the author's patients the common carotid was tied and the patient developed laryngeal palsy and hemiplegia. Early operation may permit of removal of the tumor without tying the common carotid artery. In a second case the author was able to accomplish this. My first case led me to agree with Reclus that these tumors should be let alone unless they are productive of dangerous symptoms. I have come to the conclusion that the time to operate is early, long before there are dangerous symptoms. To wait for obvious malignancy is to court failure or disaster.

The Thymus Gland.—This bilobed ductless gland becomes fully developed toward the end of the second year of life. From that period it remains stationary for a time and then undergoes retrogression. At puberty retrogression becomes rapid. Finally, the gland almost entirely disappears, although a small vestige of it usually remains through life. Studied in the very young child, it is found to consist of a thoracic portion and a cervical portion. The chief part of the gland lies directly back of the sternum and upper four costal cartilages of each side in the superior and anterior mediastinal spaces. On each side are the pleura and lung. Posteriorly it lies upon the pericardium, superior vena cava, innominate vein, and pulmonary artery. The two lobes from the gland rise into the neck in front of the trachea. The left lobe overlaps the common carotid; the right lobe, the innominate artery. A strand of fibrous tissue usually passes from the lobe which ascends highest to the corresponding lobe of the thyroid gland. The lobes of the thymus receive numerous veins from the thyroids. The inferior thyroid artery is the chief source of arterial blood. The thymus is composed of many lobules separated by septa. The undegenerated thymus contains both lymphoid and epithelial structure.

The cells of the reticulum are epithelial. In the medulla of the lobules are the concentric corpuscles of Hassall which are derived from the epithelium of the reticulum. The small thymic cells are probably lymphocytes. In Hammar's words: "The thymus is an epithelial organ which is permeated with lymphocytes" (quoted by Charles H. Mayo and Bernard F. McGrath in their thorough and impressive study of "The Surgical Importance of the Thymus." See "Collected Papers by the Staff of St. Mary's Hospital," Mayo Clinic, 1912).

The function of the thymus is as yet undetermined. Some believe it is merely a lymphatic structure and furnishes no internal secretion. Others believe that it furnishes an internal secretion of great, perhaps of essential, importance in development. Some observers believe that the thymus destroys toxins, and that deficiency of thymus permits the accumulation of toxic matter in the system. These studies of hypothymization were made on thymectomized animals.

Experiments to determine the result of excessive thymus function (hyperthymization) are peculiarly contradictory, unsatisfactory, and inconclusive. In these experiments thymus glands have been implanted, thymus juice has been injected, and thymus feeding has been practised.

Mayo and McGrath (Ibid.) conclude "that the thymic function is concerned in the general process of nutrition, particularly with the ossification of bone"; further, it is probable "that the thymus and the chromaffin portion of the adrenals act antagonistically on the sympathetic."

Although the thymus should have practically disappeared between the twelfth and twentieth year, there are cases in which it fails to disappear at all. There may never have been any symptoms to suggest persistence and the gland may be discovered at a necropsy.

The thymus gland may enlarge. The enlargement is most usual in childhood, but if the thymus is persistent, may occur much later in life. The condition is hypertrophy or hyperplasia. Enlargement of the gland may be met with in exophthalmic goiter, leukemia, Hodgkin's disease, and status lymphaticus. It may produce no symptoms whatever. It may be responsible for asthma and for sudden death (thymic asthma and thymic death). Enlargement is recognized by the *x*-rays.

Infectious and wasting diseases in children may cause atrophy of the thymus. The gland may be the seat of hemorrhages, inflammation, tuberculosis, calculi formation, and necrosis (in diphtheria). In congenital syphilis the thymus may be the seat of gummata or fibrosis.

Dubois's abscesses occur in syphilis of the thymus. Many spaces form and the spaces are full of a fluid resembling pus or actually being pus.

Enlargement by tumors may occur. Innocent tumors (fibroma, myxoma, and adenoma) are rare. Malignant tumors (carcinoma and sarcoma) are more common. The most common growths are small-celled sarcomata.

Tumors of the thymus cause the symptoms of mediastinal tumor (cyanosis, dyspnea, exophthalmus, cough, alterations in voice, circulatory disturbance).

Status Lymphaticus (*Status Thymicus; Lymphatism*).—This condition is associated with enlargement of the thymus. (See page 225.)

Operations for Thymus Enlargement or Tumor.—(See Oliver, in "Archiv. gén. d. Chir.," vi, 138, 1912.)

To perform *exothymopexy* expose the thymus by an incision above the sternum, catch the gland and capsule with forceps, draw them up as far as possible, and suture to the fascia. This operation is without much value. A decompression operation can be done by resecting the manubrium. It does not cure, but may give relief.

Thymectomy has been performed a number of times. It may be extracapsular or intracapsular, partial or complete. In 42 reported cases there were 15 deaths.

XXXIV. DISEASES AND INJURIES OF THE LYMPHATICS

Wounds, Ruptures, and Occlusions of the Left Thoracic Duct.—It was long believed that wounds of any part of the thoracic duct were almost certainly fatal. It is now known that wounds of the duct at the root of the neck are rarely very dangerous unless the duct is divided close to the vein. A wound of the duct is rarely seen as the result of an accident because the adjacent vital structures are apt to be injured at the same time and death rapidly ensues. Wounds of the duct or of its large branches occasionally, but very rarely, are inflicted during surgical operations. Benetau speaks of 12 cases thus inflicted; in 8 cases the operation was for tuberculous glands, in 3 for malignant glands, and in 1 for ligation of the subclavian artery. One alleged danger of wound of the duct is entrance of air into the adjacent vein. This is said to have happened in 1 case. As a rule, the short end of the cut duct does not bleed, the duct valves preventing hemorrhage. In Fullerton's case, when a grooved director was passed along the stump of the duct by way of a terminal into the vein, blood at once appeared. In most cases the injury is not recognized at the time, but later, when white fluid escapes from the wound. The discharge may continue or may cease spontaneously. If it continues, there is rapid loss of flesh and strength. I assisted Dr. Keen in the case in which he did recognize the wound at the time it was inflicted. A thin fluid was observed flowing rhythmically from a tear in the duct. It is to be remembered that the course of the cervical part of the duct is very variable and sometimes the duct lies very high above the clavicle. There was 1 death in 17 recorded cases (Dudley P. Allen and C. E. Briggs, in "Amer. Med.," Sept. 21, 1901).

The discharge from a cut duct may continue to leak—perhaps a pint or more flowing out during twenty-four hours. If leakage continues, constitutional effects will sooner or later become evident. In Schoff's case ("Wien. klin Woch.," Nov. 28, 1901) it was not known that the duct had been injured until the stitches were removed from the wound in the neck. The wound was found distended with chyle and Schoff packed it with iodoform gauze. Fifteen days later the patient died from chylothorax and pulmonary compression.

Rupture of the thoracic duct or of the receptaculum chyli may occur from traumatism or be a secondary consequence of tuberculosis or carcinoma.

Rupture leads to death by starvation, or to fatal compression by the exuded fluid (Harvey W. Cushing, in "Annals of Surgery," June, 1898). Occlusion of the main duct may be followed by rupture of the receptaculum chyli. Gradual occlusion by a tuberculous or inflammatory growth may not produce any serious symptoms. Cushing assumes that in such a case the lymph-current is reversed and is taken up by the right thoracic duct. In gradual obstruction masses of dilated lymph-vessels may be found, particularly in the thorax and abdomen. If lymph-vessels rupture, chyle flows out and, according to the situation, there arises "chylous ascites, chylothorax, chyluria, or chylous diarrhea" (Ibid.).

Treatment of Wounds.—If the wound in the neck does not completely divide the duct, and if the duct wound is discovered at the time of operation, suture the duct. Allen sutured the duct and had no further leakage. Keen sutured the duct and recovery followed. If the duct is completely divided, follow Cushing's advice: "It would seem advisable to place a provisional ligature about the duct on the proximal side of the wound, and to control the leakage, if possible, by a gauze tampon. This would act as a safety-valve, and allow chyle to escape, if the pressure in the duct became too great and there was difficulty in establishing a collateral lymphatic circulation. The patient meanwhile should be given a meager diet. If the leakage should become uncontrollable and threaten starvation, the provisional ligature should be tied, with the hope of a final readjustment of collateral circulation or trusting in the presence of some anomalous anastomotic branch which might suffice to carry the lymph into the venous circulation" (Ibid.). Fullerton tied both ends of a divided duct and the patient recovered ("Brit. Med. Jour.," June 16, 1906). Deanesley ("Lancet," Dec. 26, 1903) inserted the divided duct into the internal jugular vein and sutured it in place. There was some leakage, but recovery ensued. After ligation the duct on the proximal side of the ligature may distend greatly and may actually rupture. When a wounded duct is leaking the patient should be fed exclusively on proteins. The diet should be scanty and the patient must be kept absolutely quiet in order to keep pressure in the duct at as low a level as possible during the establishment of a collateral lymphatic circulation (Fullerton, Loc. cit.).

Lymphangitis is inflammation of lymphatic vessels. *Reticular* or *capillary* lymphangitis (erysipeloid), which is inflammation of lymphatic radicles, is seen in some circumscribed inflammation of the skin. It is apt to attack the hands, causing redness and swelling, fading at the point of initial trouble while it spreads at the periphery; it is caused by micro-organisms derived from decomposing animal matter (see page 198). Erysipelas also causes it (see page 199). *Tubular* lymphangitis, which is due to the entry into the lymphatic ducts of virulent micro-organisms or toxic materials, is seen after the infliction of dissecting wounds, septic wounds, snake-bites, etc. It is announced by edema and by minute, hard, red streaks running from the wound up the extremity. Suppuration may occur.

Septic or **infective lymphadenitis,** or inflammation of the glands, may follow lymphangitis or may be due to the deposition of infective material, the lymph-vessels not being inflamed. In this form of lymphadenitis there are pain, tenderness, and swelling; in severe cases there are a chill and a septic fever. Suppuration may arise.

The **treatment** is to drain and asepticize the wound, to apply iodin, blue ointment, or ichthyol over the glands and vessels, and to employ rest, heat, and compression. Internally, milk-punch, quinin, and nourishing diet are required. If the glands do not rapidly diminish in size after disinfection of a wound, and if they are in an accessible region, extirpate them. If suppuration of the glands occurs, incise and drain.

Acute lymphadenitis, or acute inflammation of the lymphatic glands, may be due to tubercle, syphilis, glanders, cold, or traumatism. Suppuration may or may not occur. In inflammatory lymphadenitis there are pain, heat, and nodular swelling. In severe cases there is fever.

The *treatment* is to asepticize any area of infection, place the glands at rest, apply heat and ichthyol ointment, or inject into the gland every day 5 minims of a 3 per cent. solution of carbolic acid to prevent suppuration. If the glands do not rapidly shrink, extirpate them. If pus forms, evacuate it, drain, and asepticize.

Chronic lymphadenitis is almost invariably syphilitic or tuberculous. It requires constitutional treatment and the local use of ichthyol, iodin, or blue ointment. If these remedies are not rapidly successful, tuberculous glands should be removed, but syphilitic glands rarely require such radical treatment.

Lymphangiectasis (*varicose lymphatics*), or dilatation of the lymphatic vessels, is due to obstruction. It may be congenital (macroglossia; lymphatic nevus, see page 368). It may be acquired. Many external causes may produce obstruction; for instance, the removal or suppurative annihilation of a considerable group of lymphatics; pressure of a scar or of a new growth upon lymph-vessels; tuberculosis or neoplasm of a group of glands. In many cases of external pressure upon lymphatics there is no lymphangiectasis because the lymph finds other channels. In fact, it has been proved that ligation of a large lymphatic trunk is not of necessity followed by lymphangiectasis. Even when the condition arises from external pressure, it is usually temporary, although, particularly if glandular tumors exist, it may be permanent.

The persistent cases are usually due to obstruction within the ducts, for instance, endothelial proliferation as a result of chronic lymphangitis, or recurrent attacks of acute capillary lymphangitis (erysipelas) or ordinary acute lymphangitis; or tuberculosis and other chronic infections. There may be such a condition as primary intralymphatic endothelial proliferation ("Med. Record," Sept. 6, 1902). Blocking with *filarial worms* may occur, and if it does, the lymphangiectasis is usually situated in the pubic, the inguinal, or the scrotal region, or on the inner side of the thigh. There are two forms of lymphangiectasis: the *varicose*, in which the vessels have a tortuous outline, like varicose veins, but are covered only with surface epithelium; and *lymphatic warts* (*lymphangioma circumscriptum*), in which wart-like masses spring up, these masses being covered with epithelium and filled with lymph. In most cases of lymphangiectasis there is considerable hard edema (*lymphedema*). Lymphangiectasis sometimes develops in an upper extremity after removing the axillary glands, and in the lower extremity after removing the inguinal glands. Periodic attacks of pain and redness occur in the area of lymphangiectasis, and usually at such times fever develops. Rupture of the dilated vessels causes a flow of lymph (*lymphorrhea*). Infection and erysipelas are apt to occur; it may be over and over again. It is uncertain whether these repeated attacks of erysipelas cause and maintain or are predisposed to by lymphangiectasis.

Treatment.—If the entire area can be removed, it should be extirpated. Maitland ("Brit. Med. Jour.," Jan. 25, 1902) shows that many varices are local and can be removed. If the varices are only partially removed, lymphorrhea will probably develop.

Lymphangioma is an advanced stage of lymphangiectasis (see page 368).

The **treatment** in mild cases is to pierce each vesicle with the negative pole of a galvanic battery and pass a current. In severe cases destroy the mass with the Paquelin cautery or excise it with a knife or with scissors.

Elephantiasis.—*True* elephantiasis (elephantiasis Arabum) is chronic hypertrophy of the skin and subcutaneous tissues following upon a lymphangi-

ectasis produced by a nematode worm (the Filaria sanguinis hominis). The disease is only encountered in the tropics. Elephantiasis of the scrotum is called *lymph-scrotum.* Elephantiasis of the leg is called *Barbadoes leg.*

Spurious or *pseudo*-elephantiasis (Fig. 815) is hypertrophy of the skin and subcutaneous tissue due to chronic inflammation (for instance, in a leg which possesses an ancient ulcer, or in the scrotum of a man with urinary fistula).

The **treatment** of true elephantiasis is massage and bandaging, sometimes ligation of the artery of supply, extirpation, or amputation.

Tuberculous Glands.—(See page 250.)

Lymphadenoma (*Malignant Lymphoma; Hodgkin's Disease; Pseudo-leukemia*).—The term "lymphoma" is used loosely to designate any persistent swelling of a lymphatic gland or glands. Lymphadenoma means a swelling of lymph-glands or lymphadenoid tissue, which swelling is progressive in character, involves group after group of glands, is associated with anemia, and often accompanied by secondary growths in the abdominal viscera.

This disease is most common in those under forty, and affects males far more frequently than females. In many cases the disease arises slowly in apparently healthy glands, and exists for some time before it takes on signs of malignancy and invades distant glands. In some cases the disease has a tendency to generalization from the start; in others it appears to remain localized for many months. A gland enlarged from irritation or from tuberculous disease may become lymphadenomatous, and tubercle bacilli can sometimes be found in lymphadenomatous glands. Lazarus asserts that the disease is lymphosarcoma and the tuberculosis accidental. Musser, Sternberg, and others believe that tuberculosis is the disease. Some few believe that lymphadenoma is really tuberculosis, but this view seems to have been definitely disproved.

Fig. 815.—Spurious elephantiasis. No filariæ found. Born and lived in Philadelphia.

That the disease is at least similar to sarcoma seems certain. That it is a variety of sarcoma is highly probable. In Hodgkin's disease Coley's fluid (the mixed toxins of erysipelas and Bacillus prodigiosus) causes reaction as in sarcoma. There is a form of tuberculosis strongly resembling Hodgkin's disease, but I do not believe that the two processes are identical. The glandular and splenic enlargements are neoplastic and not hyperplastic. The new tissue formed is called lymphadenoid tissue and, according to Banti, it is often atypical, tends to invade glandular trabeculæ and capsules, sometimes adjacent tissue, and gives origin to metastases.

Leukemia and pseudoleukemia are closely related, and both, according to Banti, are sarcoma. In leukemia the influence that stimulates proliferation falls chiefly upon the bone-marrow; in Hodgkin's disease, upon the lymph-

nodes (Neumann, quoted by Coley, in a forceful article maintaining that Hodgkin's disease is a type of sarcoma, "Trans. Am. Surg. Assoc.," 1908).

Symptoms.—The glands in the neck are usually involved first, but the disease may begin in the axillary glands, the thoracic glands, or the intra-abdominal glands.

Two or more regions are sometimes involved simultaneously or almost simultaneously.

When the disease begins in the neck it affects at first one side, and after many weeks or months the other side becomes involved. The glands are at first hard, separated from each other, movable, and the skin moves freely over them. Later the large glands weld together and form great masses upon both sides of the neck and in the axillæ, which may obstruct respiration.

After a time a very large mass may break through its capsule and infiltrate adjacent structures, and in very rare cases the skin becomes adherent and finally breaks. Intrathoracic symptoms point to involvement of the thoracic glands. It may be possible to palpate enlarged abdominal glands.

The leukocytes may be increased to 20,000 or more, but in many cases the count is normal and the relative proportion of the varieties remains normal. In a certain percentage of cases, without any increase in the number of leukocytes, there is great relative lymphocytosis. Early in the case the number of red cells may be unaffected, but after a time anemia develops. A fall in hemoglobin is noted early and this fall is somewhat more rapid than the decrease of erythrocytes ("Clinical Hematology," by J. C. DaCosta, Jr.).

The spleen is enlarged; the thyroid may be enlarged. When anemia becomes marked there are the ordinary symptoms which go with it, viz., palpitation, breathlessness, indigestion, vertigo, headache, pallor, and sometimes epistaxis. Occasionally, without obvious reason, the glands suddenly increase in size or rapidly undergo a notable but temporary diminution.

Slight fever exists at times in many cases, and ague-like paroxysms may occur. During the existence of fever the glands usually increase rapidly in size.

Diagnosis.—In a widespread case the diagnosis is easy; in a localized case it is difficult. True tuberculous glands are most apt to first appear in the submaxillary triangle; lymphadenomatous glands, in the root of the neck or in the occipital triangle. Tuberculous adenitis is most common in children. As a rule, tuberculous glands caseate, but they may remain localized for years if caseation does not occur. The tuberculous glands usually soon become adherent and immovable. Lymphadenoma is most common after twenty, rarely remains localized for more than a few months, rarely softens unless very large, and the glands are separated and movable until a huge mass forms. Early softening, prolonged limitation to one region, and absence of pronounced anemia in a person under twenty point to tubercle. In doubtful cases a gland should be removed for microscopical and bacteriological study.

In widespread tuberculous lymphatic involvement, simulating Hodgkin's disease, fever is far more likely to be present than in Hodgkin's disease. LaRoy ("Archives Internat. de Chir.," 1907, vol. iii) says that tuberculous glands are but little improved by the *x*-rays (a statement I do not altogether endorse), whereas, enlargements in Hodgkin's disease may be greatly benefited, and that in tuberculous conditions there is no particular tendency to hemorrhage and there often is in Hodgkin's disease. Coley ("Trans. Am. Surg. Assoc.," 1908) shows that the patients with Hodgkin's disease react strongly to the toxins of erysipelas.

Prognosis.—The disease is almost always, if not invariably, fatal. Most cases die within three years, some die within six months, some few live four or five years or more.

Treatment.—If the glands are localized to one side of the neck, or even

to both sides of the neck, remove them. Early removal before dissemination has occurred may possibly save the patient. If early or radical removal is not possible, do not operate, but treat the patient with nutritious food, tonics, course of arsenic, the mixed toxins of erysipelas and the Bacillus prodigiosus, and applications of the *x*-rays. Coley treated 2 cases by the mixed toxins. In both cases the lymphatic, hepatic, and splenic enlargements entirely disappeared ("Surg., Gynec., and Obst.," August, 1911). Efforts are now being made to obtain a curative serum. Beck makes nucleoprotein serum from the glands of cases of Hodgkin's disease.

XXXV. BANDAGES

A bandage is a fibrous material which is rolled up and is then employed to retain dressings, applications, or appliances to a part, to make pressure, or to correct deformity. It may be composed of flannel, of calico, of unbleached muslin, of plain gauze, of gauze infiltrated with plaster of Paris or soaked in silicate of sodium, or of gauze wet with corrosive sublimate solution. Unbleached muslin, which is the best material for general use, is washed to remove the sizing, is torn into strips, and the edges are stripped of selvage. One end is folded to the extent of 6 inches, this is folded upon itself again and again until a firm center is formed, and over this center the bandage is rolled. In a well-rolled bandage the center cannot be pushed out of the roll. A roller bandage is divided into the initial end, which is within the roll, the body or rolled part, and the terminal end, which is free. In applying a bandage the outer surface of the terminal end is first laid upon the part.

A *cylindrical* part of the body may be covered by a *circular* bandage, each turn exactly covering the previous turns. A *conical* part may be covered by a *spiral* bandage, each turn ascending a little higher than the previous turn. As each turn of a spiral bandage is tight at its upper and loose at its lower edge, the *reverse* was devised to correct this inequality; hence a conical part should be covered by a *spiral reversed* bandage. To make a reverse, hold the roller in the right hand, start the bandage obliquely upward (do not have more than 6 inches of slack), place the thumb across the fresh turn, fold the bandage down without traction, and do not make traction until the turn has been carried well around the limb. A projecting point is covered with *figure-of-8* turns. The groin, shoulder, breast, or axilla can be covered by figure-of-8 turns, each succeeding turn ascending and covering two-thirds of the previous turn and forming a figure like "the leaves of an ear of corn." Such a figure is called a "spica." In bandaging an extremity the peripheral turns should be tighter than the turns nearer the body. Never apply a tight bandage to the leg or the arm without including the foot or the hand. In firm dressings of the forearm and arm it is well to leave the ends of the fingers exposed, and use them as an index of the condition of the circulation in the part. In firm dressings of the leg and thigh leave the toes exposed.

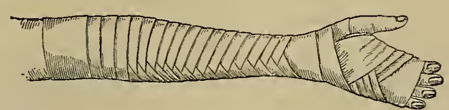

Fig. 816.—Spiral reversed bandage of the upper extremity.

Spiral Reversed Bandage of the Upper Extremity.—To apply this form of bandage use a roller $2\frac{1}{2}$ inches wide and 8 yards long. Take a circular turn about the wrist, and a second turn to hold the first; pass obliquely across the back of the hand to the extremities of the fingers; ascend the hand to the root of the thumb by several spiral turns; cover the wrist by ascending figure-of-8 turns; ascend the forearm by spiral reversed turns; cover the elbow by a figure-of-8, and the arm by

spiral reversed turns; end the bandage by two circular turns, and pin them together (Fig. 816).

Spiral Bandage of All the Fingers (*Gauntlet*).—The gauntlet bandage requires a roller 1 inch wide and 3 yards long. Take two circular turns around the wrist, pass obliquely across the wrist to the root of the thumb, and descend to its tip by spiral turns; cover in the thumb by ascending spiral turns, and return to the wrist. Cover successively each finger in the same manner, and terminate by two circular turns around the wrist (Fig. 817).

Fig. 817.—Gauntlet bandage.

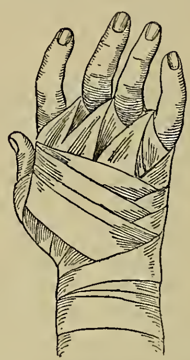

Fig. 818.—Demigauntlet bandage.

Spiral Bandage of the Palm or Dorsum of the Hand (*Demigauntlet*).—The demigauntlet requires a roller 1 inch wide and 3 yards long. This bandage has only a limited value; it must not be applied tightly, as it makes much pressure at the finger-roots, but leaves the fingers free. If it is desired to cover the palm, supinate the hand; if to cover the dorsum, pronate the hand. Take two circular turns around the wrist, sweep around the root of the thumb, and return to the point of origin. Treat each finger in the same way. End by circular turns around the wrist (Fig. 818).

Spica of the Thumb.—For this bandage use a roller 1 inch wide and 3 yards long. Start at the wrist, and reach the tip of the thumb as in applying

Fig. 819.—Spica of the thumb.

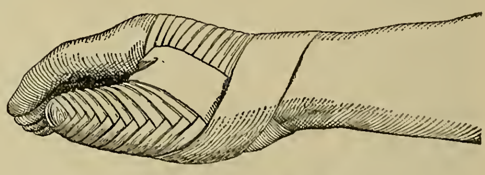

Fig. 820.—Selva's thumb bandage applied.

a spiral bandage of a finger. Make a series of ascending figure-of-8 turns between thumb and wrist, each ascending turn overlying two-thirds of the previous turn; terminate with a circular of the wrist (Fig. 819).

Selva's Thumb Bandage (Fig. 820).—Lay the terminal end of the bandage on the outer side of the second phalanx of the thumb, near the base of the phalanx. Carry it over the palmar side of the pulp of the last phalanx to the inner side of the second phalanx. The surgeon holds this turn in place with his left thumb and index-finger. The roller is returned in a recurrent manner to its place of origin, overlaps the preceding turn, and is placed as much as possible on the dorsum. The roller is carried over the dorsum of the terminal phalanx and is turned around the tip, the loop crossing over the center of the nail.

Figure-of-8 turns are now made over the dorsum of the hand, over the palm, and returning to the terminal phalanx, and an ascending spica is made.[1]

Spiral Reversed Bandage of the Lower Extremity.—Take a roller $2\frac{1}{2}$ inches wide and 7 yards long, and make two circular turns just above the malleoli, and an oblique turn across the dorsum of the foot to the metatarso-phalangeal articulation; make a circular turn, and cover the foot with ascending spiral reversed turns; return to the ankle by a figure-of-8; ascend the leg by spiral reverses; cover the knee by a figure-of-8, and the thigh by spiral reverses; terminate by two circular turns (Fig. 821).

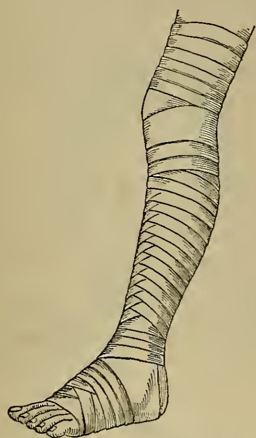

Fig. 821.—Spiral reversed bandage of the lower extremity.

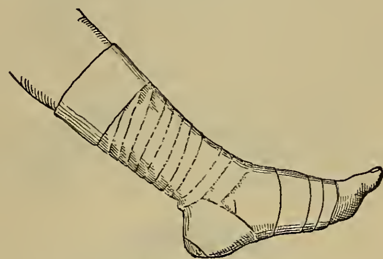

Fig. 822.—Method of covering the heel.

Bandage of the Foot Covering the Heel (*American Bandage of the Foot*).—Take a roller $2\frac{1}{2}$ inches wide and 7 yards long. The bandage is begun as a spiral reversed bandage of the lower extremity. After the foot is well covered by ascending spiral reversed turns, carry the bandage directly around the point of the heel and return to the instep; from this point carry it around the back of the ankle, down the side of the heel, under the heel, up to the instep, around the ankle in the opposite direction, down the opposite side of the heel, and under the heel and up to the instep; take the roller to above the malleoli, and end by a circular turn (Fig. 822).

Fig. 823.—Figure-of-8 bandage of the ankle.

Fig. 824.—Spica of the instep.

Bandage of the Foot Not Covering the Heel (*French Method*).—Take a roller $2\frac{1}{2}$ inches wide and 6 yards long. Make a spiral reversed bandage of the foot and a figure-of-8 of the ankle-joint (Fig. 823).

Spiral Bandage of the Foot Covering the Heel (*Ribbail's Bandage; Spica of the Instep*).—Take a roller $2\frac{1}{2}$ inches wide and 6 yards long. Apply as a spiral reversed bandage of the lower extremity until the metatarsus is well covered. Carry the bandage, parallel with the margin of the foot (the inner

[1] "Medical News," Sept. 28, 1895.

or outer margin, according as to whether it is the left foot or the right), around the posterior aspect of the heel, along the opposite margin of the foot to cross the original turn at the median line of the dorsum. Make a number of these ascending turns, each turn covering in three-fourths of the previous turn; terminate by circular turns above the ankle (Fig. 824).

Crossed Bandage of Both Eyes (*Figure-of-8 of Both Eyes*).—Take a roller 2 inches wide and 6 yards long. Make a circular turn around the forehead from right to left, a second turn to hold the first, a turn downward over the left eye, under the left ear, around the back of the neck, and upward under the right ear and over the right eye; repeat these turns, and terminate by a circular turn of the forehead (Fig. 825).

Borsch's eye-bandage is convenient and useful (Fig. 827). A narrow bandage is laid along the head and permitted to hang down the face in front of the sound eye. A circular bandage is applied around both eyes, and over the narrow bandage (A). The narrow strip is lifted and pinned, and the sound eye is thus uncovered. Of course, the posterior end of A should first be pinned to the circular turn.

Barton's Bandage (*Figure-of-8 of the Jaw and Occiput*).—Take a roller 2 inches wide and 5 yards long. Place the initial extremity of the bandage behind the inion; pass over the right parietal bone, across the vertex, down the left

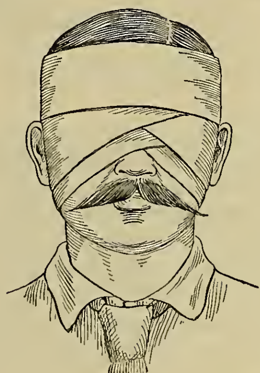

Fig. 825.—Crossed figure-of-8 bandage of both eyes.

Fig. 826.—Barton's bandage or figure-of-8 of the jaw.

side in front of the ear, under the chin, up the right side in front of the ear, across the vertex, and across the left parietal bone to the point of origin. A turn is now taken forward along the right side of the jaw to the chin, and backward along the left side of the jaw from the chin to the nape of the neck; repeat these turns, and pin the points of junction (Fig. 826). In Barton's bandage the ear lies in an uncovered triangle. The bandage may be finished by circular turns around the forehead. Barton's bandage is used for fracture of the lower jaw.

Gibson's Bandage.—Take a roller 2 inches wide and 6 yards long. Make three vertical turns around the head and the jaw in front of the ear; reverse the bandage above the level of the ear, and carry it horizontally around the forehead and head three times; drop the bandage to the nape of the neck, and take three turns around the neck and jaw; terminate by taking from the nape of the neck a half-turn upward, carrying the bandage forward to the forehead, and pinning it over the neck and over the forehead. Pin each point of junction (Fig. 828). Gibson's bandage is used for fracture of the lower jaw.

Crossed Bandage of the Angle of the Jaw (*Oblique Bandage of the Jaw*).—Take a roller 2 inches wide and 6 yards long. Make a circular turn

around the forehead toward the affected side; and a second turn to hold the first; take the turn to the back of the neck; carry it forward on the sound side, under the ear and chin; now make a series of turns around the head and jaw, in front of the ear on the injured side, but back of the ear on the sound side: these turns successively *advance* on the injured side only; terminate by going backward under the ear of the sound side to the nape of the neck, and then by

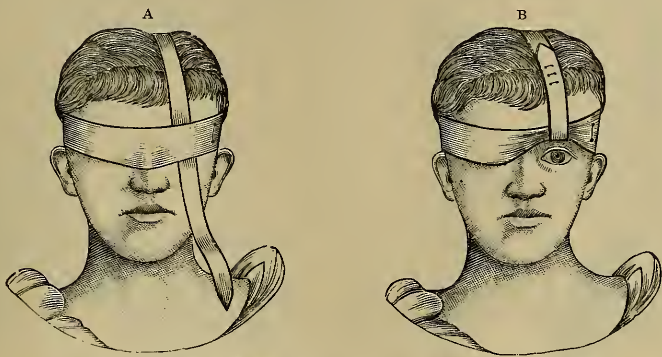

Fig. 827.—Borsch's eye-bandage: A, First step; B, second step.

taking two circular turns around the forehead (Fig. 829). This bandage is used for fractures of the ramus of the jaw and for holding dressings upon the face and the cranium.

Spica of the Groin (*Figure-of-8 of the Thigh and Pelvis*).—For one groin the roller is 3 inches wide and 7 yards long; for both groins, 3 inches wide and 10 yards long. Take two circular turns, from right to left, around the waist, then down over the front of the right groin, around the back of the thigh, up over the front of the right groin, around the waist, down over the front of the left groin, round the back of the thigh, up over the left groin, and around the

Fig. 828.—Gibson's bandage.

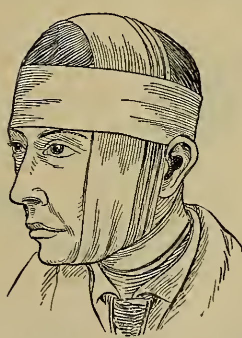

Fig. 829.—Oblique or crossed bandage of the angle of the jaw.

waist. The map being thus laid out, the turns are continued and ascended, each turn overlying one-third of the previous turn, and the bandage is completed by a circular turn around the waist (Fig. 830). Pin the crossed pieces.

Spica of the Shoulder.—Take a roller $2\frac{1}{2}$ inches wide and 7 yards long. Make a circular turn and several spiral reversed turns around the upper arm; then, coming from behind forward, carry the bandage over the shoulder, across the front of the chest, through the opposite arm-pit, and return across the back to the shoulder. Make successive and advancing turns (Fig. 831).

Figure-of-8 bandages of the elbow, both shoulders (posterior figure-of-8), the neck and axilla are shown in Figs. 832, 833, and 834.

A figure-of-8 bandage of the breast is shown in Fig. 839.

Velpeau's Bandage.—Take a roller $2\frac{1}{2}$ inches wide and 10 yards long. Place the palm of the hand of the injured side upon the shoulder of the sound side, interposing cotton between the arm and the side. Start the bandage at the axilla of the sound side posteriorly, carry it across the back to the shoulder of the injured side, down the front of the arm and under the arm just above the elbow, returning to the point of origin; repeat this turn, but, on reaching the axilla the second time, cross the back and pass around the chest, including the arm; keep on with these turns, each alternate turn going over the injured clavicle, each alternate turn encircling the arm and the body, the first turns advancing and the second turns ascending (Fig. 835). Pin the crossed pieces. This bandage is used for fracture of the clavicle.

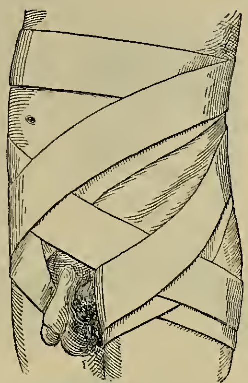

Fig. 830.—Spica of the groin.

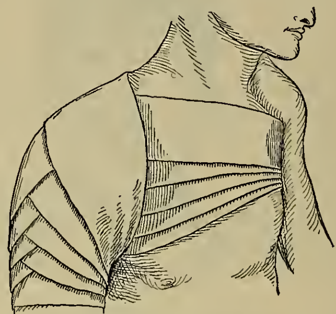

Fig. 831.—Spica of the shoulder.

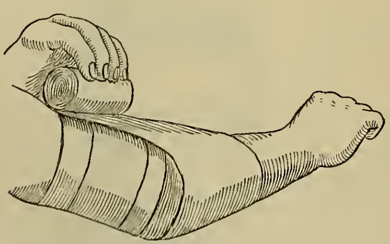

Fig. 832.—Figure-of-8 bandage of the elbow.

Fig. 833.—Posterior figure-of-8 of both shoulders.

Desault's Apparatus.—This apparatus consists of three rollers, a pad, and a sling. Each roller is $2\frac{1}{2}$ inches wide and 7 yards long. The pad, which is wedge shaped, is inserted into the axilla with the base up. The *first roller* is used to hold the pad (Fig. 836). The *second roller* binds the arm to the side over the pad. This pad is a fulcrum, the shoulder is the weight, the arm is the lever, and the second roller of Desault corrects the inward deformity of a fractured clavicle (Fig. 837). The *third roller* corrects the downward and forward displacement. It starts in the axilla of the sound side anteriorly, crosses the chest to the shoulder of the injured side, runs down the back of the arm, around the elbow, and crosses the chest to the point of origin, forming the anterior triangle; it is now carried through the axilla of the sound side to the

back, crosses the back to the shoulder of the injured side, runs down the front of the arm, around the elbow, and across the back to the axilla of the sound

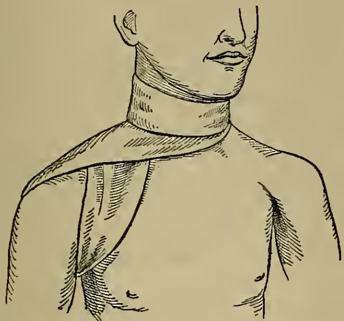

Fig. 834.—Figure-of-8 of neck and axilla.

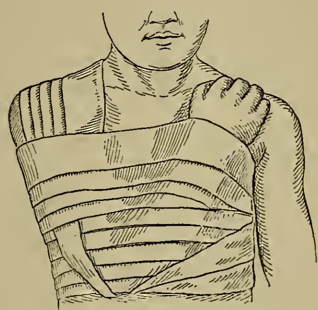

Fig. 835.—Velpeau's bandage.

side, forming the posterior triangle (Fig. 838). The formula for the Desault bandage is: start in the axilla of the sound side anteriorly, run from the axilla

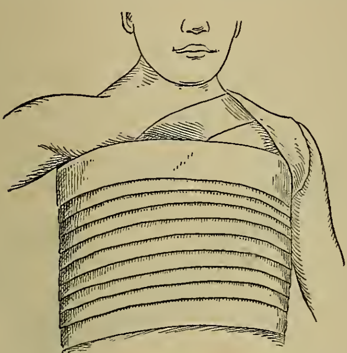

Fig. 836.—Desault's bandage, first roller.

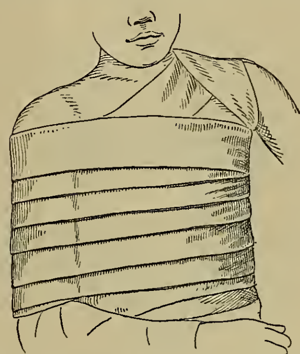

Fig. 837.—Desault's bandage, second roller.

to the shoulder, from the shoulder to the elbow, from the elbow to the axilla, and pass to the back; from the axilla to the shoulder, from the shoulder to the

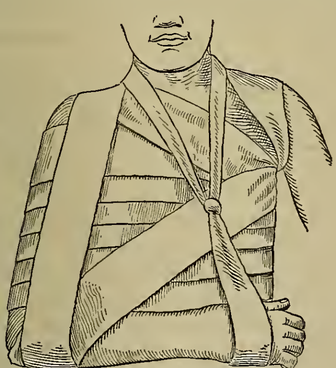

Fig. 838.—Desault's bandage, third roller.

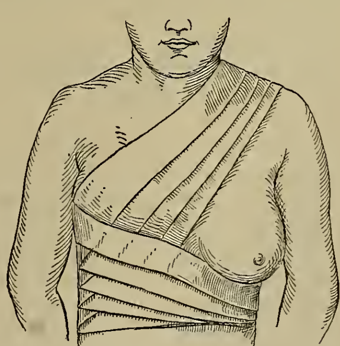

Fig. 839.—Figure-of-8 bandage of the breast.

elbow, from the elbow to the axilla, and pass to the front. Pin the crossed pieces and hang the hand in a sling (Fig. 838).

Recurrent Bandage of the Head.—Take a roller 2 inches wide and 6 yards long. Make two circular turns horizontally around the forehead and head; when the middle of the forehead is reached, catch the bandage, take a half-turn, carry the bandage to the occiput, let an assistant catch it, take a half-turn, bring the roller forward to the forehead, covering a portion of the preceding turn; continue this process until the scalp is well covered; terminate with two circular turns around the forehead and head (Fig. 840). It is often advisable to take a turn around the head and chin. Pin the crossed pieces.

Recurrent Bandage of a Stump.—Take a roller 2 inches wide and 6 yards long. Make two light circular turns around the root of the stump; make recurrent turns covering the stump as is done in covering the head; take a circular turn around the root of the stump, oblique turns to the top of the stump, circular turns around the tip, and apply an ascending spiral reversed bandage (Fig. 841)

T=Bandage of the Perineum.—Pass the transverse part around the body above the iliac crests, and pin it in front; bring one of the tails over the dressing and up between the thigh and the genitals of one side, and the other tail over the dressing and up between the thigh and the genitals of the opposite side; secure these tails to the horizontal band.

Fig. 840.—Recurrent bandage of the head.

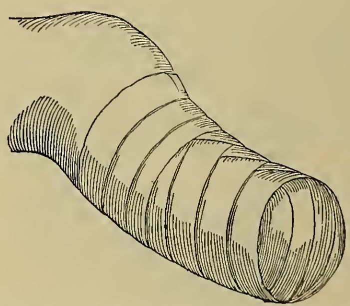

Fig 841.—Recurrent bandage of a stump.

Handkerchief Bandages.—Take unbleached muslin 1 yard square. The muslin folded once makes an *oblong* bandage; bringing its diagonal angles together makes a *triangle* bandage; a *cravat* is formed by folding a triangle bandage from summit to base; a *cord* is a twisted cravat. The triangle makes an admirable sling.

Fixed Dressings.—**Plaster-of-Paris Bandage.**—Cover the extremity with a cotton or flannel bandage or with a woolen stocking. Take a gauze roller infiltrated with plaster and place it endwise in a basin of tepid water, the water covering the plaster. When bubbles cease to arise, squeeze the bandage and apply it *without much tension*, smoothing out each turn with a moistened hand. As each bandage is taken from the basin drop a fresh one into the water. Apply four thicknesses of bandage, and finish the dressing by sprinkling dry plaster over the bandage and smoothing it with wet hands. The ordinary plaster will set in from fifteen to thirty minutes. If it is desired to have it set more rapidly, put a tablespoonful of salt in each pint of water used; if to have it set more slowly, pour stale beer into the water. The plaster bandage is removed by sawing it down the front or by moistening with dilute hydrochloric acid and then cutting through the moistened line with a strong knife. Gigli has devised a mode of application which enables us to remove the dressing with ease. A layer of cotton is placed

around the limb. A piece of parchment paper which has been wet and shaken out is placed over the cotton. A cord greased with vaselin is laid upon the paper in a position corresponding to the line we will wish to saw through the plaster. Apply the plaster bandage and see that the ends of the cord project beyond the bandage. When desiring to remove the bandage take a steel wire, make nicks on one side of it by means of a file, and attach the string to the wire. Pull the wire under the bandage. Attach each end of the wire to a wooden handle and saw through the plaster.[1]

Silicate of Sodium Dressing.—Protect the part as is done for a plaster bandage. Bandage the limb *loosely* with an ordinary gauze bandage, paint this bandage with silicate of sodium, apply another bandage and paint it, and so on until six layers are applied. Gauze bandages are better than ordinary bandages to take up silicate of sodium. Silicate dressings require from twelve to eighteen hours to dry, and they are removed by softening with warm water and then cutting.

XXXVI. PLASTIC SURGERY

Plastic surgery includes operations for the repair of deficiencies, for the replacement of lost parts, for the restoration of function in parts tied down by scars, and for the correction of disfiguring projections. Many reparative operations have been devised. Among them are: cheiloplasty, or the construction of a new lip; the closure of a cleft in the palate, the lip, or the penis; the making of a new nose; skin-grafting; grafting of muscle or tendon; nerve-grafting; the introduction of celluloid or metal into the tissues to act as a support; the injection of paraffin into the tissues to amend a depression; the diminution in the size of a lip or a nose; the amendment of protuberant ears; the correction of distortion due to cicatrices; excision of scars; closure of congenital sinuses and of fistulæ; and removal of disfiguring growths.

The subject of plastic surgery is very extensive, and a treatise upon it should be consulted if one wishes to obtain detailed and comprehensive information.

A plastic operation can be successful after lupus only when the disease has been cured. It is useless to do a plastic operation during active syphilis, and a plastic operation for a syphilitic loss of substance is to be performed only after the patient has been thoroughly treated and the disease has been apparently cured. The first step of a plastic operation consists in making the surfaces which are to be brought together raw; the second step is the complete arrest of bleeding; the third step is the approximation of the surfaces without tension; the fourth step is to close any gap from which tissue may have been transplanted; and the final step is the application of the dressings.[2] The following are the methods used:[3]

Displacement is the method of stretching or of sliding: (1) Approximation after freshening the edges (as in harelip); (2) sliding into position after transferring tension to other localities (linear incisions to allow of stretching of the skin over large wounds). *Interpolation* is the method of borrowing material from an adjacent or a distant region or from another person: (1) *Transferring a flap with a pedicle,* which flap is put in place at once or is gradually gotten into place by a series of partial operations (as in rhinoplasty, when a flap is taken from the forehead); (2) *transplanting without a pedicle,* which is performed by placing in position and by fixing there portions of tissue recently removed from the part, from another part of the same individual, or from a lower animal (as

[1] "La Semaine Méd.," Nov. 3, 1895.
[2] "American Text-Book of Surgery."
[3] Ibid.

replacement of the button of bone after trephining, transplanting a piece of bone from a lower animal to remedy a bone defect in a human being, or the grafting of a piece of nerve from a lower animal or from an amputated human limb to remedy a loss of nerve in a human being). *Retrenchment* is the removal of redundant material and the production of cicatricial contraction.

Skin-grafting.—As long ago as 1847 Dr. Frank Hamilton partly covered an ulcer with a pediculated flap, and trusted that the uncovered portion would be healed by new skin from the flap. We may graft small pieces of epithelium taken from the patient, another person, or one of the lower animals, or may graft large pieces of epithelium. The grafts should, if possible, come from the person to be grafted. The epidermic scales may be scraped off the sound skin and grafted. Lusk has blistered the skin with cantharides and grafted portions of the epidermis. The shavings of a corn and fragments of hair roots have been used. The best plan is to cut off and transplant small bits of epidermis.

Fig. 842.—Injury caused by crush and burn. Healed by granulation in eight months. Showing a condition after removal of scar of the palm, which has been repaired by stitching in an autoplastic graft (free flap) from the thigh (George S. Brown).

Grafts may come from another person or from a lower animal, but such grafts are not so apt to grow as those obtained from the individual, and even when they do grow, fail to furnish a secure cicatrix. Frog-skin furnishes unsatisfactory grafts. Some surgeons have used bits of sponge; others, the skin of rabbits, guinea-pigs, or pups. Arnot has employed the lining membrane of a hen's egg, cut in strips and applied upon the wound with the shell-surface uppermost. Small bits of epidermis taken from a recently amputated foreskin or leg may be used.

Reverdin's Method.—This operation was devised by Reverdin in 1869. Small bits of epithelium are used, and they are taken, preferably, from the person himself. The surface to be grafted should possess healthy granulations level with the skin. Cleanse the skin from which the grafts are to come, the ulcer, and the skin about it, and, if corrosive sublimate is used, wash it away with a stream of warm normal salt solution. Thrust a sewing-needle under the epidermis to raise it, cut off the graft by a pair of scissors, and place the raw surface of the graft upon the ulcer. After applying a number of grafts, place thin pieces of gutta-percha tissue over them and extending on each side of the ulcer, and so placed as to have distinct in-

tervals between them, the gaps permitting drainage. Rubber tissue must be aseptic and moist with warm normal salt solution. Dress with a pad of aseptic gauze moistened with salt solution; place over this gauze a rubber-dam, and over the latter absorbent cotton and a bandage. In the case of a child apply a light silicate bandage. If the grafted area is very extensive or if it is in the lower extremity, put the patient in bed. In forty-eight hours remove all the dressings except the gutta-percha tissue, irrigate with normal salt solution, and reapply the dressings. All signs of the grafts will often have disappeared. In a day or two more, at the site of grafting, bluish-white spots should appear, which are islands of epidermis. Each graft is capable of forming about $\frac{1}{2}$ inch of cicatrix. Grafting also stimulates the edges of the ulcer to cicatrize and contract. At the end of seven days the special dressings can be dispensed with. The spot from which the grafts were taken is dressed antiseptically. Reverdin's method does not limit cicatricial contraction to any great degree, and the new skin is apt to break down.

Fig. 843.—Claw-hand from burn. A flap with a pedicle was taken from the chest. The pedicle was cut on ninth day.

The Ollier-Thiersch Method.—Ollier, of Lyons, in 1872 succeeded in transferring large pieces of epidermis. In 1886 Thiersch, of Leipzig, set forth the technic practically as it is employed to-day. The Ollier-Thiersch method is performed as follows: Thoroughly asepticize the ulcer, the surrounding skin, and the site from which the graft is to come (the inner side of the arm or the thigh), and wash away the mercurial preparation with normal salt solution. Apply dressings wet with salt solution. On bringing the patient into the operating room remove the dressings from the ulcer, scrape the ulcer and its edges, irrigate with salt solution, and compress to arrest hemorrhage. Grafts are then obtained by putting the prepared skin upon the stretch and cutting strips with a razor. While the razor is being used the part is constantly irrigated with salt solution. Mixter's apparatus enables one to perform this operation with great neatness and speed. This apparatus consists of a knife and an open square with sharp points on the under surface. The square is forced down upon the front of the thigh, the epidermis mounts up in the opening to above the level of the metal sides, and the grafts may be cut with ease. The graft contains the epidermis, the rete, and part of the true skin. In Halsted's clinic the skin of the thigh is made tense by pressing and drawing upon it with a piece of asepticized wood, the wood is drawn slowly along, and is followed closely by the sharp catlin, by which the surgeon cuts long grafts. The grafts are pressed into place upon the raw sur-

face, and each graft overlaps a little the edges of the wound and the adjacent grafts. The skin wound is dressed antiseptically, and the grafted area may be dressed as in Reverdin's method. If a ring of aseptic gauze be made to encircle the limb below the grafted area, and another ring above the grafted area, and if on these pads little strips of wood wrapped in aseptic gauze be laid, a cage is made, and around this cage the dressings may be applied (moist chamber plan) (Fig. 844).

Wolfe's Method.—It was pointed out by Wolfe that a piece of skin, comprising the entire thickness of that structure, can be successfully transplanted without a pedicle. The ulcer is extirpated and asepticized and bleeding is arrested. The flap is cut one-sixth larger than the surface to be covered. Fat is kept out of the graft. The bit of tissue is laid upon the wound, the edges of the graft being brought against the edges of the raw area. It is not necessary to employ sutures. The part is dressed in a moist chamber. If the graft perishes, remove it.

Subcutaneous Injection of Paraffin for Prosthetic Purposes.—The principle of injecting solidifying oils into tissues to mechanically obtain effects was first laid down by J. Leonard Corning in 1891. The use of paraffin was introduced by Gersuny to amend the deformity of a saddle-nose. It has been used to limit incontinence of feces, incontinence of urine in women, to prevent reunion of nerves after division, as a counterfeit testicle, to obliterate small-pox marks, to narrow a hernial ring, to correct sinking of the cheek after removal of the upper jaw, and for other purposes (Moszkowicz, in "Wien. klin.

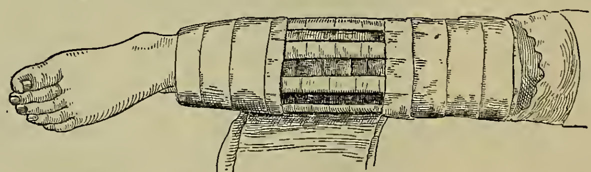

Fig. 844.—Mayer's dressing for Thiersch's method of skin-grafting ("Amer. Text-Book of Surg.").

Woch.," June 20, 1901). Paraffin is not toxic. Its injection may produce some swelling and redness, but applications of cold usually control inflammation. In two or three months the paraffin becomes hard like cartilage and encapsuled. It is questionable whether or not it is subsequently destroyed and replaced by granulation tissue. Sometimes sloughing takes place in the skin above it.

Prepare the paraffin as follows: In Gersuny's clinic solid paraffin is mixed with liquid paraffin. The melting-point of the mixture should be about 104° F. It is rendered sterile by boiling, is injected by a warm syringe, and as a semisolid, the skin having been first warmed by a hot sponge. After injection it is molded into proper shape. It sets in half a minute. It is not wise to use a mixture with a much higher melting-point, because it would possibly cause thrombosis in veins. There are difficulties and even dangers in the use of paraffin for saddle-nose. It should only be used when the skin is loose and elastic. It should never be used if there is great deformity, because then the amount required would surely cause dangerous tension. It is difficult to prevent the injected material from passing down the sides of the nose and up into the forehead. Cases of embolism causing blindness have been reported. The skin may slough if the injection is too hot or if it produces much tension.

Paraffinoma.—This term, suggested by Delangre, means an inflammatory new formation which may arise in the submucous or subcutaneous tissue about a depot of injected paraffin. It may or may not ulcerate. It is particularly apt to form in a tuberculous person. The swelling is marked and the

disfigurement great. The possibility of the formation of a paraffinoma is particularly great if paraffin is used in the subcutaneous tissue.

The only treatment is excision.

Correction of Saddle-nose By the Insertion of a Plate.—Saddle-nose is a condition in which the bones and cartilages have been destroyed by ulceration or collapsed by injury. It is useless to attempt correction by skin-flaps alone. Paraffin injections (see page 1264) may be used in the less severe cases. In a bad case we must transplant bone-flaps or insert a plate for support. The bone-flap operation is seldom satisfactory and, of necessity, creates a hideous scar. The insertion of a plate may give an excellent result, although the future is always uncertain. In 2 cases I have seen sloughing occur over the plate months after the operation. In 1 of these cases the sloughing was due to a blow from a cow's tail.

The plate used may be of silver, gold, or celluloid. An incision is made to permit the insertion of the plate. I agree with Leonard Freeman ("Annals of Surgery," August, 1907) that the incision along the bridge and the incision

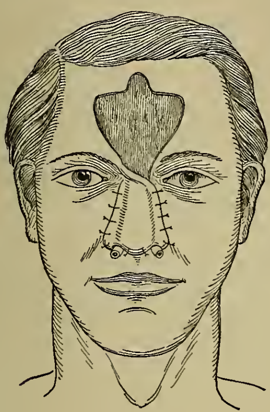

Fig. 845.—Indian method of rhinoplasty.

Fig. 846.—Italian method of rhinoplasty.

in the septum below the tip are both objectionable. The first leaves an unsightly scar and does not allow for stretching of the skin. The incision at the tip gives unsatisfactory access to the tissues requiring separation and is liable to infection from the nostril.

The best incision is Freeman's. This is a short incision across the root of the nose between the eyes. The skin is undermined along the bridge to the tip and along the sides. The undermined skin can be stretched if necessary.

Rhinoplasty.—The complete operation may be performed by transferring a flap from the forehead. This is known as the Indian operation. It was employed for centuries in India, and interest in it was awakened in England about 1820 by Mr. Carpue. The edges of the defect are made raw. A model of the desired nose, made out of gutta-percha, has its outlines marked upon the forehead, and the cut is made $\frac{1}{4}$ inch outside of the outline, so as to allow room for retraction. The flap is turned down and sutured in place (Fig. 845), care being taken not to cut off the blood-supply in the pedicle. Plugs of gauze or tubes are inserted to support the flap.

The complete operation can be performed by the Italian method (Tagliacotian method). This method was first described in Tagliacozzi's book, which was published in 1597. In this operation the flap is marked out on

the arm, is made twice the size of the desired nose, and is left attached by a broad pedicle. The nasal surface is rendered raw at proper regions, and the flap is sutured in place, the hand being held upon the head by a special apparatus (Fig. 846). The raw surface upon the arm is dressed. In about three weeks the flap is cut loose from the arm, and is pared and corrected as may be necessary.

The operations for harelip and cleft palate, and plastic operations on muscles, nerves, tendons, and bones are considered in other portions of this work.

XXXVII. DISEASES AND INJURIES OF THE GENITO-URINARY ORGANS

Hematuria.—By this term is meant the voiding of bloody urine or of pure blood, the blood arising from any portion of the urinary apparatus, and the condition being a symptom and not a disease. In hematuria the urine contains more than blood coloring-matter, it also contains blood-corpuscles. The condition in which there is coloring-matter only is called *hemoglobinuria.* Hemoglobinuria may arise after burns, etherization, and taking urotropin, and during various fevers, especially in malaria (see page 1267). Hematuria may be a symptom of disease or of injury of some part of the urinary system (calculus, acute nephritis, pyelitis, renal tuberculosis, prostatic enlargement, morbid growth, wounds or contusions of the genito-urinary tract), of blood disorganizations (purpura, scurvy, variola, leukemia, or anemia), or of metallic poisoning (mercury, lead, or arsenic). It may arise during typhoid fever, in the beginning of an acute fever (especially variola), in hemophilia, in nephralgia, in malarial fever, and in kidney infarction resulting from endocarditis. It may be caused by parasites (Filaria sanguinis-hominis and Bilharzia hæmatobia). Some drugs are renal irritants and may cause hematuria (cantharides, oil of turpentine). Oxaluria is an occasional cause. The most usual cause of renal hematuria is stone. The color of the urine in hematuria may be anything between a light pink and a decided black, but these colors may be produced by agents other than blood. (See Sollmann's "Text-Book of Pharmacology.") Carbolic and salicylic acids make urine brown or greenish black; beet-root and sorrel, the color of blood; methylene-blue, green or blue. In melanosis and splenic fever the urine becomes brown. Senna and rhubarb make an acid urine yellowish brown and an alkaline urine purple. In jaundice the urine is yellow or green. Coal-tar products may make it blackish brown. Picric acid makes it yellow. Santonin makes an acid urine yellow and an alkaline urine pink. Logwood imparts no color to acid urine, but colors alkaline urine violet or reddish. Trional, sulfonal, tar, tannic acid, and gallic acid make urine brown.

Tests for Blood.—**Spectroscopal Test.**—Bloody urine, if fresh and diluted with water, shows the two absorption bands of oxyhemoglobin. The addition of ammonium sulphid causes the two bands to give place to the band of reduced hemoglobin. If bloody urine stands for some time the four bands of methemoglobin are discovered (von Jaksch).

Heller's Test.—Add potassium hydrate to the urine and boil; a red precipitate of earthy phosphates and hematin forms. Throw the precipitate upon a filter and treat it with acetic acid; a red solution is produced, which soon fades.

Rosenthal's Test.—Take the precipitate from caustic potash, dry it, and test it for hematin; put some of the dry sediment on a slide, add a crystal of common salt, apply a cover-glass, and cause a few drops of glacial acetic acid to flow under the glass; warm, but do not boil. Teichmann's crystals will appear on cooling.

Struve's Test.—Test the urine with hydrate of potassium, and add acetic acid in excess; a dark precipitate forms, which will yield crystals of hematin when treated with sal ammoniac and glacial acetic acid.

Almen's Test (Guaiac Test).—Take 10 c.c. of urine and pour upon its surface a mixture of equal parts of tincture of guaiac and old oil of turpentine; at the point of junction of this fluid with the urine there forms a white ring which turns to a striking blue. If a man is taking iodid of potash his urine shows blue in the guaiac test.

The Benzidin Test.—This is very delicate. If the reaction cannot be obtained the urine is certainly free of blood. Add 1 c.c. of glacial acetic acid to 10 c.c. of urine. Add to the mixture one-third of its volume of ether containing a few drops of alcohol, shake, and allow to stand. The ether rises to the top, is taken off by a pipet, and is put in a test-tube in which is the benzidin mixture (0.5 c.c. of a solution of a little benzidin in 2 c.c. of glacial acetic acid and 2 c.c. of hydrogen dioxid). Blood turns the reagent green or blue within two minutes. Later the color changes to purple. (See Holland's "Medical Chemistry and Toxicology.")

Microscopical Test.—The microscope shows numerous corpuscles except in a very alkaline urine, when but few corpuscles may be found.

In hemoglobinuria—a condition sometimes occurring after burns, as a result of large doses of urotropin, and during malaria, acute febrile maladies, metallic poisoning, acute alcoholism, poisoning by mushrooms, chlorate of potash, coal-tar products, pyrogallic acid, and naphthol—there is present blood coloring-matter, which is shown by Heller's test and by Almen's test. The spectroscope shows methemoglobin. The microscope shows no corpuscles or only a few, but discloses masses of pigment. Hemoglobinuria does not occur in diseases limited to the genito-urinary tract.

Determination of the Source of the Blood.—In a woman, be sure that the bloody urine is not due to a mixture with menstrual blood. If menstruation does exist, obtain the urine for examination by a catheter. The three-glass test may be of service. Blood may be thoroughly mixed with urine. Renal blood is sure to be mixed. Bladder blood may or may not be. Blood from the urethra comes out with the first urine. The source of blood may be determined certainly only by the urethroscope, cystoscope, or urethral catheter.

Bleeding from the Kidney-substance.—Bleeding from the *pelvis* of the kidney and from the *ureter* may be due to inflammation, congestion, contusion, stone, vicarious menstruation, hemorrhagic diathesis, powerful diuretics, fevers, purpura, tumors, catheterization of the ureter, etc. Blood is thoroughly mixed with the urine and no sediment forms (smoky urine). The corpuscles are profoundly altered, are devoid of coloring-matter, and show pale-yellow rings. The severity of the hemorrhage is measured by the number of the corpuscles. Von Jaksch states that the diagnosis between renal and ureteral hemorrhage rests on the nature of the casts and epithelium present. From the pelvis of the kidney and from the ureter comes small epithelium, the cells from the superficial layers being polygonal or elliptical, those from the deeper layers being oval or irregular. In hemorrhage from the ureter the cells are few; in hemorrhage from the pelvis they are plentiful and rest upon one another like "tiles on a roof" (von Jaksch). Cells from the tubules of the kidney are small, granular, and polyhedral, have large nuclei, and are often so arranged as to form cylinders (epithelial casts). The urine during and immediately after a renal hemorrhage is apt to be acid unless alkalis have been administered, unless the bleeding has been severe, or unless pus is present in the urine. A very large renal hemorrhage may cause the passage of almost pure blood. In *renal* hematuria there are aching

in the loin, numbness of the corresponding leg, and often renal colic. The use of the cystoscope enables the surgeon to determine if the hemorrhage is vesical or renal, and if it comes from one or both kidneys. If the bladder fluid is kept clear, the blood can be seen flowing out of the ureter of the damaged organ, or if both ureters are catheterized a sample of urine can be obtained from each kidney. Even when skilfully used the ureteral catheter is apt to cause slight hemorrhage. Hence, after catheterization, microscopical hemorrhage does not count in diagnosis.

Spontaneous Hemorrhage Into the Kidney.—This may or may not cause hematuria. It may arise during nephritis or may depend on arterial disease. No lesion may be discoverable. If accompanied by hematuria it is classed as essential hematuria (see below). The bleeding may take place beneath the capsule or through a tear in the capsule into the perirenal tissue. In some cases bleeding begins in the perirenal tissue. A possible cause is aneurysm of the renal artery. There are 26 cases of this condition on record ("Lancet," Jan. 27, 1912). Spontaneous hemorrhage comes on suddenly with shock and pain in the loin. There may or may not be hematuria. A mass can be palpated. In some cases the skin becomes discolored. Always operate. If hemorrhage comes from perirenal tissue, excise the bleeding tissue. If blood comes from the kidney it is usually necessary to perform nephrectomy. In spontaneous hemorrhage blood may tear its way into the peritoneal cavity. (See article by Russell S. Fowler, in "Annals of Surgery," Dec., 1911.)

Essential Hematuria.—In this condition the ureteral catheter reveals blood from one kidney only, there being no demonstrable lesion to account for the condition. Randall, in a very comprehensive article, draws the following conclusions regarding this condition ("Jour. Am. Med. Assoc.," Jan. 4, 1913).

He divides essential hematurias into three groups: (1) Nephritis with congestion plays the leading rôle. (2) Varicosities of vessels of renal pelvis resulting from some extrinsic condition affecting the kidney circulation. (3) Hemorrhage due to rupture of capillaries or to diapedesis of red blood-corpuscles. In either of these conditions congestion probably exists.

I believe that some cases are due to unrecognized papilloma. Essential hematuria is sometimes called *unilateral hematuria*, an unfortunate name, as many cases of hematuria which do not belong to this group are unilateral.

Ureteral Catheterism.—Catheterization of the ureters may give information of the greatest value. It enables the surgeon to obtain the urine from one kidney unmixed with urine from the other kidney and uncontaminated by material from the bladder or urethra. By this method we can determine if pus, blood, bacilli, etc., come from the ureter or kidney, and from which ureter or kidney. A stricture of or a calculus in a ureter can be located; hydronephrosis and pyonephrosis can be diagnosticated; the presence of both kidneys, if either kidney is diseased or if both are diseased, and the secretory capacity of each kidney in a given time, can be ascertained. The method is also employed to treat various conditions of the ureter and kidney.

Kelly impressed upon the profession that the ureters in women can be catheterized when the patient by the knee-chest posture permits the atmospherical distention of the bladder, so that the ureteral orifices can be inspected through a speculum. Light is reflected into the speculum, a forehead mirror and an electric light being employed. It may be necessary to dilate the urethra before inserting the speculum. It is rarely necessary to give a general anesthetic. Kelly moistens a bit of cotton wrapped on a metal rod in a 10 per cent. solution of cocain, introduces it just within the external urethral orifice, and holds it there for five minutes before beginning the operation. When the ureteral orifice of one side is found by inspection through the speculum, he introduces a sterile flexible silk catheter lubricated with boroglycerid

and it is pushed up from 4 to 6 inches in the ureter. A similar tube is introduced into the other ureter and the separated urines are collected in test-tubes. (See Kelly's "Operative Gynecology.") The catheterization of the ureters by this method can be performed only by a dextrous and experienced man; but such an individual can do it with ease and celerity; as practised by Kelly himself it seems, until one tries it, the perfection of easy simplicity.

Kelly has catheterized the ureter in man by inserting a straight speculum, placing the patient in the knee-chest position to inflate the bladder with air, and introducing a metallic catheter. (For a discussion of the technic of catheterizing the ureters see Cystoscopy, page 1301.)

Segregation of urine is the method of obtaining urine separately from each ureter by segregating each ureter's supply into an artificial trough, from which it is drawn. The method is seldom used in the United States at the present time. It is painful, unreliable, and has been replaced by ureteral catheterization. In cases in which the ureters cannot be found, segregation may be employed. The three most practical segregators are Harris's, Luys's, and Cathelin's. Professor Harris, of Chicago, has devised an instrument (Fig. 847) which in some cases simplifies the problem of obtaining unmixed urine

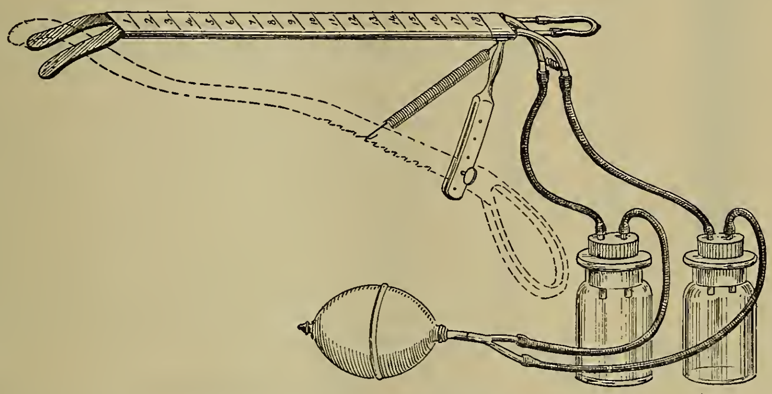

Fig. 847.—Harris's segregator fitted for use.

from each ureter. The double catheter is passed into the bladder. The lever is inserted in the rectum of the male and the vagina of the female. The lever is fastened to the perforated frame from the double catheter. The double catheter is now opened in the bladder, and the blades of the instrument are held in position by a spring. The end of the lever in the vagina or rectum humps up the floor of the bladder between the separated ends of the divided catheter, and forms a longtitudinal septum or watershed between the ureteral orifices. The end of each catheter lies in the bottom of a pocket to the side of the watershed. "By producing a very slight exhaustion of the air in the vials by means of the bulb the urine, as fast as it escapes from the ureters, drops directly into the ends of the catheters and flows at once into the vials, right and left respectively."[1]

In using this instrument place the patient flat on his back upon a table, the thighs and legs being flexed, and the feet, hips, and head being on the same level. Irrigate the bladder thoroughly with sterile water and have 150 c.c. of fluid in the bladder when the blades are opened. Leave the instrument in place for thirty minutes. It is rarely necessary to give an anesthetic. In some cases cocain must be used, and in some cases of painful cystitis ether

[1] "Jour. Cutan. and Gen.-Urin. Dis.," May, 1899.

should be given. Harris says the instrument should not be used if there is a growth of the bladder that bleeds easily, if the bladder is contracted, if there is a very large prostate or a vesical stone.[1]

In catheterization of the ureters there is always some danger of carrying infection upward from the bladder, and sometimes catheterization is impossible. It is impossible if great quantities of blood or pus make the urine opaque, or if inflammation of the bladder wall hides one or both ureteral orifices. The Harris method of segregation produces considerable pain, but is free from this danger. As a matter of fact, however, Harris's method often possesses elements of uncertainty, because the septum may not be perfect and the urine from one side sometimes contaminates the urine from the other. The separator devised by Luys in 1901 finds some warm advocates (Fig. 848). It causes less pain and accomplishes more certain results than the instruments of Harris or Cathelin. Barringer ("Am. Jour. Med. Sciences," March, 1907) points out that "there are certain classes of cases in which the separator cannot be used. They are the following: (A) Those in which the bladder capacity is less than 20 c.c.; (B) those in which the urethra is not penetrable by the instrument; and (C) those in which the base or neck of the bladder is distorted by (*a*) marked prostatic hypertrophy; (*b*) extreme anteversion or anteflexion of the uterus; (*c*) certain uterine tumors; and (*d*) marked cystocele." Catheterization of the ureters is not so safe as separation, is far more difficult, but gives more certain results.

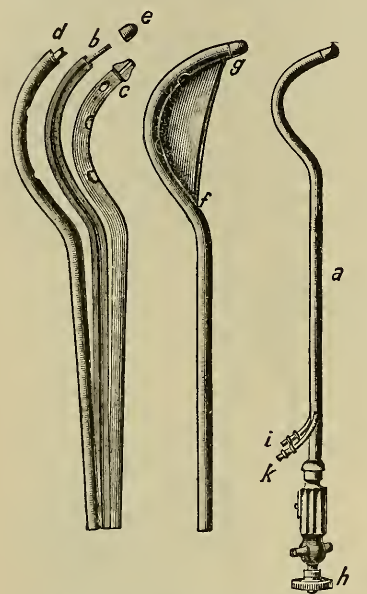

Fig. 848.—Luys's separator: *a*, The composite instrument ready for introduction; *i* and *k*, discharge tubes; *h*, screw to regulate the tension of the membrane; *b*, flat middle piece; *c* and *d*, grooved lateral portions; *e*, tip uniting the parts; *g*–*f*, rubber membrane, tense. The chain is not visible in the figure (Sahli).

Urethral Hemorrhage.—In urethral bleeding blood appears independently of micturition, or blood comes out first and is followed by clear urine. Urethral hemorrhage may arise from acute urethritis, from an inflamed stricture, from the passage of an instrument, or from some other traumatism. It may be due to a polypus, to a stone in the prostatic urethra, to violent or prolonged sexual effort.

The source of urethral hemorrhage can be ascertained by the use of the endoscope or, better, by means of the cysto-urethroscope.

Vesical hemorrhage, including hemorrhage from the prostate, may follow the relief or retention of urine (hence do not draw off all the urine at once when a bladder is distended), may be due to stone, inflammation, tumors, etc., or may arise from traumatisms, instrumental or otherwise. The color of the urine is usually bright red, but if long retained in the bladder it becomes black and often tarry. The reaction is alkaline. The clots, when floated out, are large and without definite shape. In micturition the urine is clear or only a little colored at the beginning, but becomes darker and darker as micturition continues, and as it ends the flow may consist of almost pure blood. In very small vesical hemorrhages the urine may be smoky. Crystals of triple phosphate indicate bladder disorder. The microscope shows

[1] M. I. Harris, in "Medicine," April, 1898.

colorless and swollen corpuscles and many polygonal cells. Symptoms of bladder mischief usually exist, but cystoscopical examination or exploratory suprapubic cystotomy may be required for the diagnosis.

Pain in Genito-urinary Diseases.—Pain as a symptom of genito-urinary disease may be found at some point distant from the seat of lesion. A stone in the bladder causes pain in the head of the penis just back of the meatus; stone in the kidney induces pain in the loin, the groin, the thigh, and the testicle; inflammation of the testicle causes pain in the line of the cord in the groin. In other cases of genito-urinary disease pain is felt at the seat of lesion, as in urethritis and prostatitis. Pain felt before micturition, and being relieved by the act, is found in cystitis and in retention of urine. Pain is felt during micturition in inflammation of the bladder, prostate and urethra, and in the passage of gravel or stone. Pain which is acute at the end of micturition is noted in stone in the bladder, in trigonitis or urethrocystitis (inflammation of the neck of the bladder), and in inflammation of the prostate gland. The pain caused by stone in the bladder, it may be observed, is ameliorated by rest and is aggravated by exercise unless the stone is encysted. The pain caused by acute prostatitis is intensified by defecation and the act is accompanied by the appearance at the meatus of a few drops of starch-like mucus.

Frequency of Micturition.—Frequent micturition arises from irritation of the sensory nerves, from phimosis, contracted meatus, inflammations, very acid urine, calculi, urethral stricture, and hyperesthesia of the urethra, Frequency of micturition may be due to spinal irritability from concussion or from sexual excess, from contraction of the bladder rendering the viscus unable to hold much, from worry, anxiety, fear, or from excessive urinary secretion, as in diabetes or in the first stage of contracted kidney. Frequent micturition exists in obstruction by enlarged prostate and in atony of the bladder walls. Hypersecretion of urine plus bladder intolerance is known as "nervousness of the bladder," and is found in hysteria. Frequency of micturition increased by *movement* is observed in stone and tumor of the bladder. Nocturnal frequency of micturition is present in cases of enlarged prostate and atony of the muscular walls of the bladder. Frequency of micturition with diminution of the diameter of the stream suggests a constriction of the urethral canal; frequency of micturition with diminished projectile force suggests a posterior stricture, enlarged prostate, or bladder atony. Slowness of micturition hints at enlarged prostate, atony, or urethral stricture.

Sir Henry Thompson's diagnostic questions are as follows:

"1. Have you any, and, if so, what, frequency in passing water? Is frequency more manifest during the night or the day? Is frequency more manifest during motion or rest? Does any other circumstance affect it?

"2. Is there pain on passing urine, and, if so, is it before, during, or after the act? What is its character—acute, smarting, dull, transitory, or continuous? What is its seat? Is it felt at other times, and is it produced or intensified by sudden movements?

"3. What is the character of the stream? Is it small or large; twisted or irregular; strong or weak; continuous, remitting, or intermitting? Does it come by the meatus, or partly or entirely through fistulæ?

"4. Is the character of the urine altered? What is its appearance, color, odor, reaction, and specific gravity? Is it clear or turbid, and, if turbid, is it so at the time of passing? Does it vary in quantity? Are the normal constituents increased or diminished? Does it contain abnormal elements, as albumin or sugar? What inorganic deposits are found? What organic materials are met with?

"5. Has the urine ever contained blood? If so, was the color brown or

bright red; were the blood and urine thoroughly mixed; was the blood passed at the end or at the beginning of micturition, or did it come only with the last drops of urine; or was it passed independently of micturition?

"6. Inquire as to pain in the back, loins, and hips, permanent or transitory, and for the occurrence of severe paroxysms of pain in these regions."

The Determination of the Excretory Capacity of the Kidneys in Health and in Disease.—The Phloridzin Test.—This test is made with comparative ease and may aid the surgeon in determining whether he is justified in performing some operation of convenience. It enables him to estimate with a fair amount of accuracy the capacity for elimination possessed by the kidneys. The test depends on the fact that the healthy epithelium of the glomeruli and tubes, when stimulated to activity by phloridzin, forms sugar from that drug and thus produces temporary glycosuria. When the epithelium is diseased, little or no glycosuria occurs. The test is applied as follows: The dose is about 5 to 10 mg. of phloridzin, according to the body-weight of the patient. It is administered hypodermatically, the bladder having been emptied beforehand. If the eliminating powers of the kidney are at a healthy level, sugar should appear in the urine within half an hour of the injection. If at the end of this time only a small amount of sugar can be detected, one may assume that the kidneys are affected; and if no sugar can be found, a serious renal disease may be assumed to exist.

The actual standard that is to be considered as the normal amount of sugar which should be eliminated after the administration of phloridzin is a matter of some uncertainty. It is usually estimated at 0.3 per cent., a less amount of sugar than this being taken as an evidence of renal difficulty (Watson and Bailey, in "Report of Boston City Hospital for 1902"). The sugar is separated from the phloridzin in the epithelium of the glomeruli and tubules of the cortex of the kidney. The drug seems to be entirely harmless.

It is because phloridzin is acted upon by the kidney epithelium that this test is better than the methylene-blue test. The latter does not really measure the excretory power of the kidney epithelium; it merely shows to what degree the kidney is permeable in the mechanical sense. Personally, I should not be disposed to set aside older and more thorough methods of urinary analysis for the phloridzin test, although I believe that it has a range of distinct usefulness.

The Methylene-blue Test (*The Method of Achard and Castaign*).—When methylene-blue is injected hypodermatically it normally is changed into a chromogen, appears in the urine within half an hour, and disappears in from thirty-six to forty-eight hours. If the blue color is not manifest in the urine for an hour or more, there is impairment of renal permeability. Only 50 per cent. of the amount ingested is removed by the kidneys. Accuracy in the test is not possible unless the amount of the methylene-blue actually passing into the urine in a given time is determined. The dose given hypodermatically is 0.05 gm. in 1 c.c. of sterile water. The test is unreliable and the blue color may appear in the urine in half an hour in some cases of marked kidney disease. At its best the test only indicates the freedom of mechanical renal permeability.

The Indigo-carmin Test.—This drug should be largely excreted in a few minutes. It colors the urine. It is an unreliable method. It will show functional failure, but there may be no functional failure even in organic disease. In many cases the color appears as quickly in urine from a diseased kidney as in urine from the sound organ.

This method enables us to recognize functional incapacity. By it we may forecast uremia. If the urine is collected from each ureter separately we can tell the capacity of each kidney. In this test, if color does not appear until

after twenty-five minutes, and if during the first hour less than 30 per cent. of the amount introduced is excreted, a contemplated surgical operation should be postponed or abandoned.

The Phenolsulphonephthalein Test.—This is the most reliable one. The drug is not toxic. It is given in an alkaline solution. A hypodermatic injection of 6 mg. is administered. It appears in the urine when the kidneys are normal in from six to twelve minutes, and from 40 to 60 per cent. of the amount given is excreted during the first hour. It colors urine red and a quantitative estimation can be made by means of a colorimeter. When the color first appears, and how much of the drug is excreted in the first hour, must be noted.

Cryoscopy (*Korányi's Method*).—Cryoscopy is the determination of the freezing-point of a liquid and the comparison of this with the freezing-point of distilled water. It is applied particularly to blood and urine. This method is complex and difficult of application, requires a considerable amount of fluid, and is not regarded as very valuable. The freezing-point of a fluid depends upon the number of molecules it contains. The freezing-point goes hand in hand with molecular concentration—great concentration gives a low freezing-point; little concentration, a high freezing-point. Cryoscopy of the blood and urine is used to determine the adequacy of renal activity. Normal blood freezes at about —0.56° or —0.57° C. Healthy urine freezes between —0.9° and —2° C. In renal inadequacy the freezing-point of the blood is lower than normal and the freezing-point of the urine is higher. It is held that surgical operation is contra-indicated if there is such a degree of renal inactivity that the freezing-point of the blood is at or below —0.6° C. and if the freezing-point of the urine is at or above 1° C. The urine is obtained from each kidney separately and is compared with the blood's molecular composition.

Diseases and Injuries of the Kidney and Ureter

Tumors of the Kidney.—Tumors, innocent or malignant, may arise in the kidney. Among the innocent tumors are fibroma, lipoma, angioma, and adenoma. Hypernephroma of the kidney arises from fragments of adrenal tissue included in the kidney. Hypernephromata were thought to be renal lipomata until 1883, when Grawitz showed they contained adrenal elements ("Virchow's Archiv.," xciii). The name "hypernephroma" was suggested by Birch-Hirschfeld in 1896. A hypernephroma may arise directly from the suprarenal gland or it may arise from an adrenal "rest" or aberrant gland. Such rests may be met with in the substance of the kidney, under the renal capsule, in the perirenal tissue, in the testicle, the ovary, the liver, the inguinal canal, the mesentery, among the spermatic vessels, in the broad ligament, in the renal plexus, or in the solar plexus (W. W. Keen). The term hypernephroma is applied to any growth which arises from adrenal cells "whether the growth be adenoma, carcinoma, or sarcoma in type" (Duffield, in "N. Y. Med. Jour.," May 1, 1909). The tissue of a hypernephroma is identical with the adrenal gland, and it contains fat and glycogen. The exact nature of such a tumor is unsettled. It is probably an adenoma, but some consider it to be a sarcoma and others a carcinoma. Some tumors give no evidence of malignancy; some are very malignant. A malignant hypernephroma grows rather rapidly, eventually attains a large size, and is sometimes painful. A patient in the Philadelphia Hospital from whom I removed a hypernephroma complained of tenderness in the left side and occasional attacks like renal colic during which he passed bloody urine. The tumor could be easily palpated in the left loin. The kidney was removed and resembled a huge kidney of nearly normal shape, but nodular in outline. Dr. Coplin found it to be hypernephroma. In this case there was no increase of arterial tension. The patient died. Another case

was a woman of forty-five who was brought to the Jefferson Hospital. She had suffered from pain in the loin for months. It was paroxysmal, but lacked the radiation of renal colic. Hematuria appeared long after the pain had begun. It was persistent, but small in amount. Palpation detected a tumor and the x-rays showed enlarged kidney. There was no increase of arterial tension. Recovery followed nephrectomy. In a man, aged thirty-four, in the Philadelphia Hospital there were attacks of severe pain referred to the groin, testicle, and loin. The bleeding was profuse. A mass was palpable in the right upper abdomen and loin. Examination of blood showed hemolysis, but there was no hypertension. The growth was exposed in the loin. Hemorrhage was so violent that it became necessary to open the abdomen and ligate the renal pedicle. The kidney was removed and the patient recovered.

Fig. 849.—Sarcoma of kidney with metastasis (Horwitz).

Very malignant cases have proved fatal within six weeks after symptoms were observed. Some patients have lived three years. A hypernephroma of malignant nature involves adjacent structures, and gives rise, after a time, to metastases, particularly by way of the blood. The bones are most liable to metastatic deposit, but such deposits may occur in the lungs, liver, and other regions. In a case upon which I operated for a supposed adenomatous goiter the condition was really metastatic hypernephroma. Hypernephromata are infinitely more common in the kidney than anywhere else. They tend particularly to occur in middle life. Sarcoma or carcinoma may arise in the kidney. Sarcoma is most common in the young, and may reach an enormous size (Fig. 849). A malignant tumor of the kidney produces hematuria, the urine often containing blood-casts of the ureter, kidney, and pelvis, and sometimes, though rarely, characteristic cells. Pain is often present in the loin and thigh,

and there may be colic-like attacks when clots are passing through the ureter. Emaciation is rapid and pronounced. A tumor can usually be palpated. Pyelography with a 10 per cent. solution of collargol may aid in the diagnosis (see page 1309). The only possible treatment for a malignant growth is early nephrectomy. In some few cases an innocent tumor can be removed by a partial nephrectomy. A malignant tumor requires a complete nephrectomy. In making a diagnosis of renal tumor use the cystoscope. If blood is coming from above the bladder, note if it is from one or from both ureters. Blood from both would contra-indicate nephrectomy. Before removing a kidney it is necessary to be sure that the patient is possessed of two kidneys. Note if urine flows from each ureter, or, if uncertain, catheterize the ureters.

Nephroptosis, Prolapse of the Kidney, or Mobile Kidney.—There are two forms of this condition: (1) *Movable kidney,* which is an organ freely moving back of the peritoneum, either within the cavity of its fibro-fatty capsule or entirely without its capsule (this condition is acquired); and (2) *floating* or *wandering kidney,* an organ having a mesonephron and lying within the peritoneal cavity (this rare condition is always congenital). Keen states that there may be drawn a clear theoretical distinction between movable and floating kidney, but practically there is no rigid line of demarcation, as a movable kidney may have as large a range of movement as a floating kidney. The kidney is normally somewhat mobile, and nephroptosis is considered to exist only when the range of movement exceeds distinctly what is normal. Normally, on inspiration the kidney descends about $\frac{1}{2}$ inch. It is seldom that a normal kidney can be palpated in men, but in most women the right kidney can be palpated, and in some women the left organ can also be felt. Harris ("Jour. Amer. Med. Assoc.," June 1, 1901) describes three degrees of movable kidney. In cases of the first degree, one-half of the organ can be distinctly grasped and the kidney can be made to recede. In cases of the second degree both hands can be brought together above the kidney. In cases of the third degree the kidney has descended as low as the pelvic brim or has moved to or beyond the umbilicus. The organ may drop below the brim of the pelvis, may cross the vertebral column, or may reach the anterior abdominal wall. When a movable kidney becomes fixed in an abnormal situation, the organ is spoken of as *dislocated.*

Women suffer from movable kidney more often than do men. Küster estimates that 4.41 per cent. of women examined in general surgical practice have movable kidney. Edebohls finds it in 20 per cent., and Harris in 56 per cent., of cases in gynecological practice. In about one-half of the cases it gives rise to little or no trouble. A movable kidney is found in the great majority of cases upon the right side. In many cases it is bilateral, the right kidney being usually the most mobile. Splanchnoptosis may be associated with acquired nephroptosis. Floating kidney is always congenital. Movability of the kidney is occasionally, but rarely, found in children, though congenital cases occasionally occur. In a congenital case there is not splanchnoptosis. Tuffier has reported 3 cases in children six, nine, and ten years of age respectively, and J. Cromby reported 18 cases of floating kidney in children, the youngest patient being three months of age (quoted by Harris, Ibid.). Among the assigned causes of the movable condition are to be named traumatism; strains; abdominal-wall laxity from pregnancy, removal of a tumor, or tapping for ascites; absorption of peritoneal fat from wasting disease (Edebohls); tight lacing; uterine displacements; and enteroptosis leading to traction on the transverse mesocolon. The condition is certainly often associated with ptosis of the other abdominal viscera (enteroptosis, gastroptosis, etc.).

Traumatism is rarely the immediate and essential cause of a true movable

kidney. In some cases people assert that pain began immediately after a blow, an attack of coughing, violent vomiting, lifting, straining at stool, a fall, or in parturition. In such cases the kidney may have been mobile before the accident. Again, pain is not proof of the inauguration of movability. It is probable, however, that traumatism may loosen the kidney and that mobility may subsequently develop. Gutterbock says that a kidney in normal relations cannot be rendered mobile by a simple fall or a trivial force. Loosening can be induced only by rupturing surrounding tissues; and if this happens, symptoms of a distinct nature will indicate the seat of injury. Becher and Lennhoff claimed that there is a connection between movability of the kidney and the length and breadth of the body. They have laid down a formula, viz.: Measure the distance from the suprasternal notch to the crest of the pubes. Divide this by the smallest circumference of the abdomen. Multiply the product by 100. The result is the abdominal index. If the index is greater than 75 there is a tendency to movable kidney. If it is less than 75 there is no such tendency. Harris makes out a strong case for the view that the condition is due to the relation existing between the location of the kidney and the body form. He divides the body into three zones: The upper zone contains the lungs and heart. The middle contains the liver, stomach, spleen, pancreas, and the greater part of each kidney. The lower contains the intestinal canal and the lesser part of each kidney. When there is a naturally small or a diminished capacity of the middle zone, the kidney is displaced downward. The right kidney is pressed upon by the heavy liver, which drives it down; the left kidney is pressed upon by the comparatively small spleen. Hence movable kidney is more common on the right side than on the left. The upper pole of the kidney is first pushed forward and then the entire organ descends (M. L. Harris, in "Jour. Amer. Med. Assoc.," June 1, 1901). Harris maintains that the amount of mobility depends upon the degree of contraction of the middle zone and upon internal traumatisms (lifting, straining, coughing, etc.).

Symptoms of Both Forms.—There may be no discomfort whatever, or the patient may be a confirmed invalid. The usual symptoms are epigastric pain (just to the left of the middle line), which disappears when the kidney is replaced, dragging pain in the loin, and paroxysms like nephritic colic. Sudden attacks of violent pain in the kidney or stomach may occur—attacks which are accompanied by nausea, vomiting, great weakness or collapse, vertigo, chills, and subsequently elevated temperature (*Dietl's crises*). Dietl's crises are due to kinking or twisting of the ureter or renal vessels or to inflammation of the kidney. They may be caused by physical exertion or indiscretion in diet and may be followed by hydronephrosis or strangulation of the renal vessels. A few years ago I operated upon a man suffering from a violent and prolonged crisis and found a twist of the vessels and ureter. In a Dietl's crisis there is congestion or strangulation or both. An incomplete or temporary twist of the renal pedicle may induce simply pain in the abdomen and loin, hematuria, albuminuria, and cylindruria.

The question as to whether or not abdominal pain is due to movable kidney is sometimes in doubt. The localization of the pain may lead us to suspect appendicitis. Some surgeons think that catarrhal appendicitis is often associated with movable kidney, but I do not think the association is common. "Dr. Kelly has shown us how to solve this doubtful question between appendicular pain and the pain of movable kidney. He catheterizes each ureter separately, and introduces into each catheter as much fluid as the renal pelvis will hold without causing pain. He then measures this fluid from each side, and determines whether it is in excess of an estimated average. If it is in excess, he is sure that dilatation has begun. He then injects the

kidney again, with the deliberate purpose of producing pain; and if the patient recognizes this pain due to the distention as of the same character and in the same position as that which he has previously felt, Dr. Kelly assumes that the pain has been due to the kidney, and not to the appendix, and recommends an operation to fix the kidney" (the author, in "New York Med. Jour.," August 4, 1906). Usually in a case of movable kidney there is a sense of a moving body in the abdomen, and the patient has aggravated indigestion, often accompanied by vomiting. Constipation is the rule, and violent attacks of cardiac palpitation are common. Most subjects of kidney mobility are extremely nervous—many of them hysterical or hypochondriacal. Persistent vasomotor paresis causes cold hands and feet and often albuminuria. Temporary jaundice is not uncommon. There is frequently irritability of the bladder. Vertigo and insomnia are present in many cases. The patient cannot sleep when lying on the sound side (Goelet). In women the sexual organs are almost invariably deranged, and menstruation aggravates the pain and discomfort. All the symptoms are intensified by exertion and are modified by rest. The urine is normal except after violent exercise, when it may contain blood. Splanchnoptosis may also exist, and if it does, the pulsations of the abdominal aorta are strongly noticeable because that structure is bared by gastroptosis. The proof of the existence of movable kidney is the finding of a mass, movable on respiration, change of position, and palpation, shaped like that organ, pressure upon which occasions no sensation or causes pain or a sickening feeling. A "lumbar recess" (Morris) may sometimes be found, and percussion over the loin gives resonance. In some cases a movable kidney can be readily detected when the patient stands up, but is difficult to find when he is recumbent. Franks's method of examination is very satisfactory in most cases (Fig. 850). The patient is placed recumbent. If dealing with a right kidney, the surgeon stands to the right side and pushes four fingers of his left hand in the loin below the twelfth rib, and rests the thumb lightly in front just below the ribs. The patient takes a full breath and holds it a moment, and just before he empties his lungs the surgeon presses his thumb up deeply below the ribs. During expiration the thumb follows the liver, and the fingers press toward the front. If with the right hand the kidney can be felt entirely below the left hand, the case is one of movable kidney. If such a condition is detected, press hard with the right hand, and gradually loosen the grasp of the left hand, and the kidney will slip between the fingers and ascend. A normally mobile kidney descends so that its lower end can be felt, but it moves back during expiration.[1] Goelet uses Kendal Franks's method of palpation, but has the patient stand, with the weight resting on the leg of the sound side and with the leg of the impaired side slightly flexed and resting on the toes. The body leans a little forward. A movable kidney must not be mistaken for a distended gall-blad-

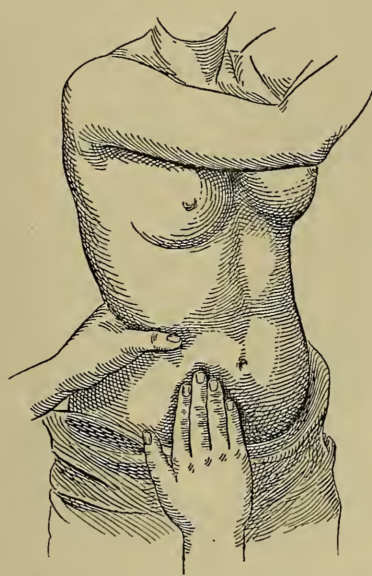

Fig. 850.—A. H. Goelet's method of palpation for the detection of a prolapsed kidney.

[1] "Brit. Med. Jour.," Oct. 12, 1895.

der, a tumor of the mesentery, stomach, or omentum, a phantom tumor, an ovarian tumor, or a cancer of the pancreas. A distended gall-bladder can be pushed upward, but not backward, and not downward unless the liver is movable; it is extremely tender, and cannot be pushed out of reach. A kidney can be pushed upward and backward—in fact, in all directions. An enlarged gall-bladder can always be palpated. A movable kidney which is not enlarged can be felt at times and not at others (Henry Morris). A movable kidney may pass between the examiner's fingers, and if pushed into the loin, it tends to remain; but if a distended gall-bladder is pushed into the loin, it springs out as soon as pressure is relaxed (Henry Morris). The x-ray study of the kidney pelvis after injection with collargol is known as *pyelography* (see page 1310). The x-ray picture of a kidney so injected is a pyelogram. This method is of the highest diagnostic value. It will always show a displaced kidney, and it indicates hydronephrosis. One picture should be taken with the patient standing, another with the patient recumbent. It is important to remember that in about one-half of the cases of movable right kidney the left kidney is also movable, but to a less degree. Appendicitis is thought by some to be more frequent in individuals with movable right kidney than in those free from renal mobility. Sometimes a movable kidney endangers life, rupture of the kidney, twisting or rupture of the ureter, or strangulation of the renal vessels occurring, the ultimate cause of death being albuminuria, uremia, or hydronephrosis.

Treatment.—Mobile kidney is treated as follows: If the kidney is but slightly mobile and there are no local symptoms, the treatment should be non-operative: (1) The *rest treatment of S. Weir Mitchell* may be tried; it often markedly mitigates the symptoms, but does not seem to cure. (2) *Mechanical support* should always be tried. The most satisfactory mode of applying it is by the corset recommended by Gallant ("Am. Jour. Obstet.," July, 1901). This corset is long and straight in front, and when applied, fits firmly over the hips and lower abdomen, less firmly at the waist, and least firmly above.

The patient lies down, a pillow being under the buttocks and the knees being drawn up. While in this attitude the corset is put on and it is laced from below up. If the attempt to apply the corset develops tenderness, keep the patient at rest in bed until it can be applied without pain. In some cases conservative treatment is not indicated; in others it fails.

In every case of very movable kidney and in some cases in which movability is not great operation is indicated.

"In a case in which the kidney exhibits trivial movability, but in which the range of mobility is found to be gradually and certainly increasing, or in any case of kidney movability in which there are distinct local symptoms, operation is indicated. The distinct local symptoms mean the beginning of actual harm to the kidney, and the progressive increase of movability means the ultimate attainment of a wide range of movement. A kidney which is widely movable may at any time twist upon the ureter and the renal vessels; and it is certain to suffer from partial or slight twists, probably many times repeated in the twenty-four hours, even if a severe twist does not occur. A deduction from the foregoing statements is that a patient suffering with nephroptosis, even when the mobility is slight, should be examined at regular intervals, to note whether the area of movement is extending, or whether local symptoms have arisen. Three local symptoms that should be regarded as indications for operation are severe pain in the renal region, distinct tenderness of the kidney, and enlargement of the kidney" (the author, in "New York Med. Jour.," August 4, 1906). Billington ("Brit. Med. Jour.," May 1, 1909) formulates the following indications for operation:

1. When renal pain is so severe or persistent as to cause serious inconvenience. The ordinary dragging pain in the loin is not an indication. Billington refers to severe pain due to perirenal inflammation, ureteral obstruction, or impeded venous return.

2. When there are harassing and depressing gastric and colonic troubles (gross lesions being absent).

3. Cases of spinal and cerebral neurasthenia.

4. Cases of lunacy. Personally I do not operate on groups 3 and 4 unless there are signs of grave renal disaster.

The usual operation chosen will be nephropexy, very seldom nephrectomy. (1) *Nephropexy* is the operation employed in most instances (see page 1296). It is the author's experience that if the patient has had marked nervous symptoms for a long time, nephropexy will rarely cause them to pass away permanently, even though the kidney remains firmly anchored. (2) *Nephrectomy* is necessary only in very rare cases; it may be done for dislocated kidney, when grave kidney disease exists, or when nephropexy has failed in a case of great severity.

In many cases of this trouble no operation should be performed, the use of Gallant's corset securing, perhaps, decided or complete relief. I do not operate if the kidney is only slightly movable and if there are no local symptoms or if there are merely the general symptoms of hysteria. If the mobility is slight and the hysterical and neurotic condition is pronounced, anchoring the kidney will not cure the nervous condition. In these nervous cases, associated with prolapse of the kidney, there is usually also prolapse of the other abdominal viscera; and both kidneys are, as a rule, movable, the right, however, in most cases being decidedly more movable than the left.

If there is but slight mobility of the kidney, but the range of movement is, week by week and month by month, increasing, or if we find a case of movable kidney in which there are distinct symptoms, an operation should be performed. The existence of definite local symptoms means beginning harm to the kidney; and if we find the area of movement gradually increasing, we know that eventually it will become extensive. Any widely movable kidney may twist the ureter and the renal vessels, producing serious trouble or even disaster, and consequently should be fixed by operation. Even if a severe twist does not take place, the kidney is bound to suffer from partial or slight twists. Such kidneys will eventually become hydronephrotic. The meaning of the term "slight mobility" is indicated on a previous page (see page 1275).

One is not unusually in doubt in cases of movable kidney whether a pain indicates local trouble with the kidney or catarrhal appendicitis, because the pain may be located in the appendix region. Kelly, of Johns Hopkins Hospital, has shown how to solve this problem (see page 1276).

There are many operations for movable kidney. In all of them the kidney is exposed in the loin. Some make a vertical and some an oblique incision. Edebohls makes a vertical incision, forces the kidney out of the wound, incises the fibrous capsule longitudinally, turns a cuff down on each side, and applies sutures. These sutures traverse the kidney substance and the fold of capsule on each side. The upper suture catches the periosteum of the last rib; the other sutures catch the lumbar fascia. Drainage is not required, and the suture material employed is kangaroo-tendon or chromicized catgut.

Some surgeons simply pass sutures through the uncut capsule and the kidney substance and thus fasten the kidney to the lumbar fascia. Others split the capsule and pass sutures through the edge of the capsule and the wound edges, but not through the kidney substance.

To promise success, an operation ought to restore the kidney nearly to its normal position and fix it permanently in place. It is undesirable to inflict

damage on the kidney itself, and I do not believe in any operation that seeks to obtain fixation by passing sutures through the kidney substance. In cases in which decapsulation is performed the kidney will grow fast without any special method of suturing.

Most of the operations suggested do not place the kidney sufficiently high up to get it into a fair position. Kelly's operation gets it higher than most of them, and Goelet's operation gets it well into place. In many of the suture operations the sutures are placed in the convex surface of the kidney or the kidney capsule, and on fixing the kidney by tying the sutures there is a permanent quarter twist of the ureter—a condition that may be responsible for great pain. This may be obviated entirely by the ingenious method of Goelet ("Annals of Surgery," Dec., 1903). I believe, however, that the suture operations which do lift the kidney well up toward its proper place and in which the sutures are applied on the posterior surface and not the convexity, tilt the upper pole forward into a permanent and perhaps disastrous position. Such operations lift the kidney from below its midline and thus fix the lower half of the organ, but leave the upper half unfixed. I believe, too, that in many cases in which kidneys have been sutured they get loose again and that the best operation, after all, is that by the use of slings of iodoform gauze (see page 1296).

Injuries of the Kidney.—**Laceration** or **rupture** is caused by falls and by blows upon the back or the belly.

Symptoms.—In some cases the parenchymatous structure is torn, but the capsule is not torn, and in consequence urine and blood are not extravasated into the perirenal connective tissue or into the peritoneal cavity. In other cases the parenchyma and capsule are both torn and urine and blood are extravasated into the perirenal tissues, the peritoneal cavity, or both of these regions. The laceration may be trivial, may be considerable, or may tear the kidney apart. The symptoms depend on the gravity of the injury. A slight tear without involvement of the capsule may produce practically no symptoms at all. A more severe injury produces shock, and, if profuse bleeding occurs, the general symptoms of hemorrhage. In intraperitoneal rupture there is profuse and usually fatal hemorrhage. In laceration of the kidney there are severe pain in the loin, which shoots into the testicle, and lumbar tenderness. If there is considerable perirenal bleeding the loin will be full and dull on percussion, and if the hemorrhage is large, a palpable mass will form after a time and after some days the skin will become discolored. There is usually frequent and painful micturition, and in some cases suppression of urine. Hematuria occurs in renal laceration unless the rupture was intraperitoneal or the ureter was torn. If the rupture was intraperitoneal there are evidences of profuse internal hemorrhage, abdominal rigidity, etc. (Daniel N. Eisendrath, "Jour. Amer. Med. Assoc.," Oct. 25, 1902). It is important to remember that hematuria can arise from simple renal contusion, and that even severe kidney damage does not of necessity cause bloody urine. If there is hematuria, the use of the cystoscope, catheterization of the ureters, or the employment of Harris's segregator will demonstrate from which kidney the blood comes. A kidney laceration may be followed by secondary hemorrhage, perirenal suppuration, hydronephrosis, or pyonephrosis. The force of the injury may have caused kidney displacement.

Treatment.—In an intraperitoneal rupture laparotomy should be performed. As a rule, nephrectomy is necessary, but it may be possible to arrest hemorrhage by packing. If the shock is pronounced and if there is increasing fulness in the loin, whether hematuria exists or not, or if blood comes profusely from the ureter, whether or not there is much shock or lumbar fulness, make an exploratory lumbar incision and stop the bleeding by

packing or by a purse-string suture (Figs. 851, 852), or, if necessary, perform partial, or even complete, nephrectomy. Ordinarily, after a kidney injury, when there is not great shock, increasing lumbar swelling, or severe hematuria, treat by rest in bed and by feeding with liquid food or by nutritive enemata to prevent vomiting. Opium, tannic acid, or gallic acid may be used. Apply ice-bags to the loin and the side of the abdomen, and after bleeding ceases strap the loin and apply a binder. If large blood-clots in the bladder cause pain or retention of urine, introduce a catheter and inject the bladder with boric acid, or use the tube and evacuator of a Bigelow apparatus. If this procedure fails, open the bladder by a suprapubic incision and drain.

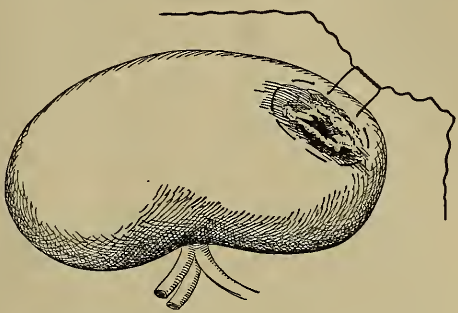

Fig. 851.—Purse-string suture applied to a perforation (after Schacher).

Results of Operation.—Up to 1894 there had never been a case of intraperitoneal rupture operated upon. During the following seven years 6 were operated upon and all recovered (Daniel N. Eisendrath, "Jour. Amer. Med. Assoc.," Oct. 25, 1902). Küster collected 47 cases of nephrectomy, and 83 per cent. recovered. Keen estimates the mortality of primary nephrectomy for rupture at 20 per cent., and of secondary nephrectomy at 38.5 per cent. Without operation intraperitoneal rupture is inevitably fatal. Of extraperitoneal ruptures, 70 per cent. recover without operation (Eisendrath). Francis S. Watson ("Boston Med. and Surg. Jour.,"

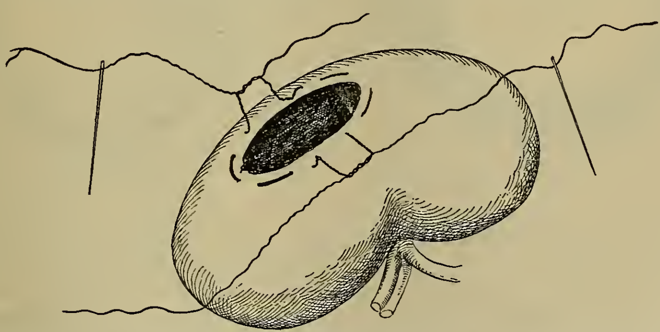

Fig. 852.—Showing the application of a double purse-string suture for the arrest of hemorrhage in large wound (after Schacher).

July 16, 1903) has collected 660 cases of subparietal injury of the kidney. The following statistics are of interest: Treated expectantly: 273 cases with 81 deaths, a mortality of 29.6 per cent. Treated by operations other than nephrectomy: 99 cases with 7 deaths, a mortality of 7.7 per cent. Treated by nephrectomy: 115 cases with 25 deaths, a mortality of 21.7 per cent.

Perforating wounds of the kidney, if purely posterior, do not involve the peritoneum; if anterior, they do. The *symptoms* are escape of blood and urine by the wound; hematuria is usual, but not invariable; pain as in rupture; the patient may be unable to micturate; and nausea, vomiting, and constitutional signs of hemorrhage exist. Traumatic peritonitis, perinephric abscess, or general sepsis may ensue. Confirm the diagnosis by exploration

with the finger after operative exposure. Extraperitoneal injuries give a good, and intraperitoneal a bad, prognosis.

Treatment.—If the wound of the kidney is extraperitoneal, enlarge the lumbar wound to permit of drainage, and arrest hemorrhage by packing and hot water or by a purse-string suture (Figs. 851, 852).

Suture of the Kidney.—The tendency of any suture material to cut through the kidney structure is great. The following simple procedure greatly lessens this danger: Cut the ordinary catgut roll into three or four parts, as shown in Fig. 853. Slip beneath the exposed loops of the purse-string suture, as shown in Fig. 854, a section of the catgut roll consisting of a series of short stiff strands. These permit fairly firm tying of the suture-ligature without cutting of the kidney structure by the suture. In nephrotomy the same procedure can be used to hold the kidney wound together.

Asepticize the wound, insert a drainage-tube down to the kidney, dress with bichlorid gauze and make frequent changes of dressings, keep the patient in bed and on a low diet, and give gallic acid and opium. In some cases nephrectomy, partal or complete, will be required. In intraperitoneal wounds perform an abdominal section and, as a rule, remove the damaged organ (see Nephrectomy).

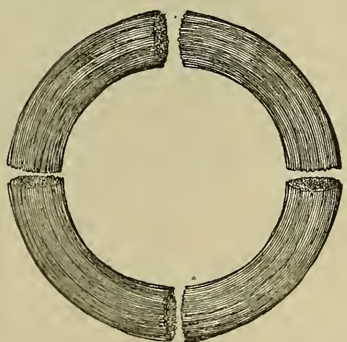

Fig. 853.—Catgut ring cut into quarters to be inserted under the suture as shown in Fig. 854.

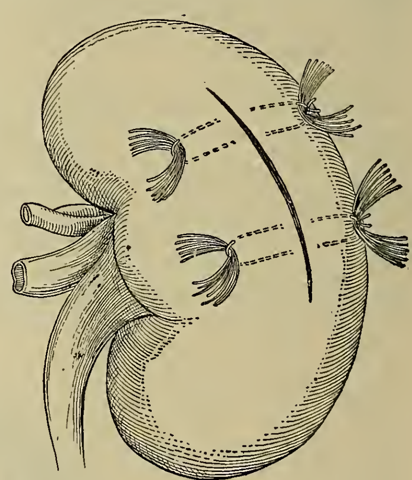

Fig. 854.—Stellwagen's suture of kidney to prevent cutting after tying.

Wounds of the Ureters.—Rupture from external violence is an extremely rare accident. Eisendrath ("Jour. Amer. Med. Assoc.," Oct. 25, 1902) found only 3 undoubted cases on record. A rupture or wound from accidental violence is almost invariably associated with other serious injuries. The ureter may be wounded accidentally by the surgeon during the performance of an abdominal operation, or it may be wounded intentionally, as in Morris's case, in which a malignant growth was incorporated with the ureter. There is particular danger of injuring the ureter in operations upon intraligamentary growths, because the ureter is displaced and often resembles an adhesion. The rule of surgery is that when working about the ureter the surgeon neither clamps nor cuts any structure without a careful preliminary examination. Rupture causes severe shock and extravasation of urine around the kidney or into the peritoneal cavity. In extraperitoneal rupture a palpable mass forms in the loin. When the ureter is divided in an operation, a flow of urine is seen.

Treatment.—The upper three-fourths of the ureter can be reached by an extraperitoneal incision, which is a prolongation of the incision for lumbar nephrectomy, running from the twelfth rib downward, and forward to 1 inch

anterior to the anterior superior spine of the ilium, and then parallel to Poupart's ligament until a point is reached above its middle (Fenger). Israel's incision begins at the anterior edge of the erector spinæ mass, one finger's length below the twelfth rib, is taken forward parallel with the rib until it reaches the line of the rib's tip, and is then carried toward the middle of Poupart's ligament until the line for ligation of the common iliac artery is reached, and is then taken toward the middle line as far as the outer border of the rectus muscle. The lower one-fourth of the ureter can be reached by abdominal section, by sacral resection, or by an incision like that for extraperitoneal ligation of the iliac vessels. The best operation to reach the lower ureter is Gibson's (see page 1299). If it seems probable that the ureter is wounded or ruptured, explore, and if this is found to be the case, endeavor to restore the continuity of the tube. A longitudinal cut can be sutured with fine catgut. If the ureter is cut across near the bladder, implant the proximal end into the bladder and ligate the distal end (Van Hook, Penrose, Kelly). If it is cut above the bladder portion, perform lateral implantation by Van Hook's method (see page 1300).

A longitudinal wound of the ureter inflicted during an abdominal operation should be sutured, but if the duct cannot be readily reached, simply make a posterior incision and drain with rubber tissue, as the longitudinal wound will heal by granulation if no sutures are inserted (Van Hook). In a case of transverse division perform uretero-ureterostomy or vesical implantation; or, if neither of these methods is feasible, make a urinary fistula in the loin or perform nephrectomy.

Renal Calculus.—A stone in the kidney is formed by the precipitation of urinary salts into the renal epithelial cells and the gluing together of these salts and cells by material from mucus or blood-clot, this mass serving as a nucleus on which accretion takes place. Most calculi escape when small, as *gravel*. The **cause** is a highly acid urine, which induces catarrh of the renal tubes. Such high concentration of urine is favored by a sedentary life, by the ingestion of much alcohol or nitrogenous food, by constipation, by an inactive skin, and by a torpid liver. The slaves of poverty are particularly liable to calculi because of the use of unsuitable foods and the formation of great amounts of nitrogenous waste. Males suffer more often than do females; certain locations favor the development of the malady, and a family tendency sometimes exists.

The **symptoms** of stone in the kidney may not appear for years after the stone forms, but generally they are manifested early. There may be no pain. There had been none in 13 cases out of 23 which came to autopsy and were reported by Clark. Usually there is pain; the severity of the pain depending upon the roughness and movability rather than upon the size of the stone. A fixed stone in the kidney and a smooth stone in the pelvis may cause little or no pain. A rough stone in the pelvis causes severe pain. The patient usually complains of pain in the loin, and sometimes of pain in the iliac region. Deep percussion over the kidney causes pain in the loin, even when pressure is painless (Jordan Lloyd's symptom). Pain is aggravated by exercise and pressure, and the kidney is usually enlarged. The urine is often somewhat albuminous, and may from time to time contain blood. Frequency of micturition is noted during the day, but seldom when at rest at night. The urine may be purulent. *Nephritic colic* is due to the washing of a calculus into the orifice of the ureter, which it blocks, tears, or distends. The pain is either sudden or gradual in onset, is fearful in intensity, and runs from the lumbar region down the corresponding thigh and spermatic cord (the testicle being retracted), and into the abdomen and back. There are nausea, vomiting, collapse, sometimes unconsciousness

or convulsions. Frequent attempts at micturition are productive of pain, but of little urine. Rectal tenesmus is common. The urine is often, but by no means always, smoky from blood. Blood may be found by the microscope when it cannot be detected by the naked eye. In rare cases fatal hemorrhage occurs. Blood is present in about one-half the cases. After a time the pain vanishes, the stone having passed into the bladder or having fallen back into the pelvis of the kidney. Slight attacks of colic occur from the passage of small stones or plugs of mucus. A calculus retained in the kidney eventually excites pyelitis, pus appears in the urine, and soreness or pain in the loin exists. Kelly says: Even if pus is found, we are not always sure from which kidney it came. Pain or swelling may point to one side, but we are not sure that the outer

Fig. 855.—Stone in kidney.

organ is not also affected. The cystoscope must be used. Bloody or purulent urine may be seen coming from one ureter. If able to pass the renal catheter into one ureter, attach a syringe, and by making suction draw out any pus which may be present. In renal calculi cases this fluid is apt to contain fragments of uric acid. By using a renal bougie coated with dental wax it may be possible to make scratches on the instrument when it comes in contact with a concretion.[1] When a stone is impacted in the renal pelvis the point of greatest tenderness on pressure is below the last rib, by the edge of the erector spinæ muscle. In septic cases there may be chills and irregular fever, and often there is leukocytosis. In most cases a stone in the kidney or ureter can be

[1] Howard Kelly, in "Med. News," Nov. 30, 1895.

skiagraphed. Nephrolithiasis may cause death by exhaustion, by sepsis, by rupture of a hydronephrosis, or by amyloid degeneration.

Treatment.—For the gravel of the uric-acid diathesis use alkalis, especially the liquor potassii citratis, and reduce the amount of nitrogen in the diet to a minimum, at the same time washing out the organs by copious drafts of water. Citrate of lithia, given in the water, is supposed to add to the therapeutic effect. Some surgeons prescribe natural lithia water. Piperazin, in doses of 5 to 8 gr. three times a day, is highly commended by some. Exercise is to be insisted on. When gravel is phosphatic, order strychnin, the mineral acids, and rest at the seaside. When oxalate of lime is found, restrict the diet, use the mineral acids, recommend travel or rest amid new surroundings, and give an occasional course of sodii phosphas, $\frac{1}{2}$ dram three times a day, taken in a natural lithia water. Nephritic colic is relieved by hypodermatic injection of morphin and atropin, a hot bath, diluent drinks, and possibly the inhalation of ether. After an attack watch all the urine passed to see if a stone appears. If one does not soon appear, use the cystoscope, and if a stone is found in the bladder, wash out that viscus with an evacuator. This is very important, as the vesical stone may fail to pass, and if it remains in the bladder it will progressively enlarge. Further, finding it proves the diagnosis of renal colic. If a stone impacts in the ureter, perform the operation of *ureterolithotomy*. The diagnosis of this impaction is in many cases aided by the x-rays, but is sometimes possible only after exploratory laparotomy. If the symptoms point to stone in the kidney, always take a skiagraph. If this shows a stone, if medical treatment fails, or has failed, and if the other kidney is not organically diseased, operate. If in doubt in spite of the skiagraph, make an exploratory lumbar incision; feel the surface of the kidney with the finger, sound the inside of the organ with a needle, or open the organ for exploration, and if a stone is detected, incise the kidney and remove the stone. Keen is of the opinion that operation should not be performed if the urea is below 1 per cent. If, after nephrolithotomy, suppression of urine occurs, cut into the other kidney, as in one-half of all cases a stone will be found lodged there. I agree with Brewer ("Med. Record," March 20, 1909) that "a kidney containing one or more calculi, and also the seat of an advanced septic process, should be removed if the opposite organ is healthy. To leave such a kidney is to invite subsequent trouble from recurrence of stone, pyonephrosis, or long-continued sepsis." I agree with him when he says: "It is also often safer to remove a kidney with multiple calculi embedded in its substance than to inflict the trauma necessary to remove them, as alarming primary or secondary hemorrhage is apt to occur." In a case of my own a most persistent postoperative hemorrhage forced me to perform nephrectomy to save life.

Calculus Impacted in the Ureter.—A ureteral calculus comes from the kidney, sometimes dropping, but more often being forced, into the tube. A stone may be arrested at any one of the points of constriction. There are three points of constriction in the ureter: one point is about 2 inches below the renal pelvis, another is at the pelvic brim, another is about $\frac{1}{2}$ inch from the bladder orifice of the ureter. The highest point has a diameter of about $\frac{1}{7}$ inch, the middle point a diameter of about $\frac{1}{4}$ inch, the lower point a diameter of about $\frac{1}{10}$ inch. A small stone may completely block the ureter. A large stone may fail to completely block it because the ureter dilates above, the stone acts as a ball-valve, and urine trickles by.

Symptoms.—Attacks of violent pain of the nature of renal colic occur, and not unusually there is a rigor with the attack and fever after it. Such an attack may be followed by hematuria. The urine should be examined microscopically during several days after a colic to see if it contains blood-cells. Tenderness

can be developed at the point of impaction, the point of greatest tenderness being in the loin *below* the level of the kidney or in the iliac region (Perkins). In stone in the ureter pain is not developed by pressure in the loin at the level of the kidney. If a stone partly obstructs the ureter, the urine is pale, of low specific gravity, and free from albumin. Impaction near the bladder causes symptoms similar to stone in the bladder (Jordan Lloyd). These symptoms are frequent micturition, pain at the seat of impaction, pain in the head of the penis, and bloody urine. If a stone is impacted in the lower end of the ureter a finger in the vagina or rectum will find tenderness and perhaps will feel the stone. In a woman, a stone lodged in front of the broad ligament may be felt by a finger in the vagina. Back of this region and up to the pelvic brim a stone may be felt by a finger in the rectum. A cystoscopic examination, in unusual cases, may show a portion of stone projecting from a ureter (Kelly). Impaction near the kidney is accompanied by hematuria and pyuria, lumbar pain, pain radiating into the groin, thigh, or testicle, and retraction of the testicle. These symptoms are identical in character with the symptoms caused by stone in the renal pelvis. Complete obstruction of the ureter causes hydronephrosis. Pyonephrosis results from infection of a hydronephrosis. In some cases a stone acts as a ball-valve, plugs the ureter for a time, during which a lumbar mass develops, and then allows the urine to flow. A copious flow of urine is accompanied by disappearance of the lumbar mass. Complete urinary suppression may follow blocking of a ureter by a calculus. If a ureteral catheter tipped with wax is introduced, a calculus will make distinct scratches upon it (Kelly). The Cunningham catheter (see Fig. 866, *e*) may assist in detecting a stone. It has not been successful in our hands when the stone was impacted more than 6 c.c. above the ureteral outlet. This catheter may also be of assistance in dislodging the stone.

The *x*-rays are very valuable in diagnosis. A pyelographic study of the ureter and pelvis may give material assistance.

Treatment.—During a painful paroxysm give morphin and use hot packs. Belladonna is useful by inducing relaxation of spasm. The ozonized oil of turpentine, given in capsules in 10-min. doses, is often valuable. It was employed by the elder Gross. For the pain Bransford Lewis ("Jour. Am. Med. Assoc.," Jan. 29, 1910) catheterizes the ureter and injects into the renal pelvis 20 min. of a 1 per cent. solution of alypin (monohydrochlorid of benzoyl). Alypin is a powder. It is soluble in water and is to be sterilized by boiling for not over five minutes. The attack may terminate and not return, because the calculus passes. If such an attack does pass away, the urine should be examined after every act of micturition to see if the stone is voided from the bladder. After a day or two, if the stone does not appear, use the cystoscope, perhaps catheterize the ureter, and thus discover if the stone is in the bladder or if it is impacted. If the stone is in the bladder, use the Bigelow evacuator to effect removal, or crush the stone by the small forceps of Bransford Lewis or by the forceps of Leo Buerger. The stone must never be allowed to remain, as it will surely enlarge and cause subsequent trouble. If a stone is found impacted in the ureter have the patient drink water freely. Sterile olive oil may be injected into the ureter through a ureteral catheter, or the ureteral orifice may be dilated by a suitable bougie. If the impacted stone is very near the bladder the ureteral orifice may be slit. Simple catheterization of the ureter may be followed by expulsion of the stone. If in spite of these procedures the stone remains impacted in the ureter, the question of operation presents itself. An impacted stone is certainly a peril, but how immediate the danger it is often impossible to say. In some cases stones have remained impacted for many years without doing obvious harm. In other cases the kidney is rapidly destroyed. The stone may pass after having been retained

for a long time, and drinking freely of water favors its expulsion. One of my cases had long had a retained stone, came to the hospital for operation, and passed the stone. Sooner or later a retained stone will lead to disaster and it ought to be removed by operation. It will cause, if retained, thickening or ulceration of the ureter, dilatation of the ureter above it, and kidney trouble. A lodged stone increases gradually in size and other stones may form above it. The extraperitoneal operation is to be chosen in most cases. Even when the stone is impacted below the pelvic brim, it is usually better to do the extraperitoneal operation. (See Ureterolithotomy.)

Abscess of the kidney may be caused by traümatism, by calculus, by stricture of the ureter, by disease of the bladder, by the union of miliary abscesses (tuberculosis), by pyemia, and by certain parasites.

The **symptoms** are pus in the urine (this is usual, but not invariable), hematuria in traumatic cases, and pain running into the groin. The urine in most cases is alkaline. Constitutional symptoms of suppuration exist, the fever being far higher than that generally met with in renal tuberculosis. The bladder should be examined with a cystoscope to determine that the turbid urine flows from the ureter and to identify the diseased side. It is well, if possible, to catheterize the ureters.

The **treatment** in the early stage is rest, morphin, purgation, anodynes, and hot fomentations. In some cases repeated lavage through the ureter may cure. When the diagnosis is clear, and lavage fails or is not thought desirable, incise the loin, open the kidney and stitch it to the abdominal wall, or, if the organ be badly damaged, remove it.

Pyelitis and **pyelonephritis,** which usually affect only one gland, are caused by urethral stricture, by stopping of the ureter by blood-clot, by vesical paralysis, by stone in the bladder or in the kidney, by enlargement of the prostate gland, by ascending tuberculous or gonococcic infection, by growths in the calices, and by certain drugs. It is said to occasionally arise from large doses of oil of sandalwood or urotropin. Such drugs could not furnish pus cells and, at most, could only irritate and thus predispose by lowering resistance. Rare cases are due to hematogenous infection by tubercle bacilli. The colon bacillus is the organism most often responsible.

Symptoms.—A patient who has, or who has had, retention of urine develops high fever, often preceded by a chill, and headache, stupor, and dry tongue are noted. Unlike acute Bright's disease, there is neither edema nor dry skin, convulsions do not occur, the urine is plentiful and contains pus, but rarely blood. The **prognosis** is very bad.

The **treatment** is to remove the obstruction if possible. If the urine be acid, give liquor potassii citratis; if alklaine, give benzoic acid. Gallic acid, eucalyptol, and small doses of copaiba or cubebs are recommended. Venice turpentine, camphor, and opium may be given in pill form. Quinin is used to stimulate the patient. The bladder is to be washed out every day with boric acid solution (3 gr. to 1 oz. of water). Cups, dry or moist, and hot sand-bags or bran-bags are to be applied to the loin. Alcohol may be sparingly administered. Urotropin is a useful drug. Lavage of the pelvis by means of the hydrostatic apparatus shown in Fig. 874 may be practised and is often most useful. For lavage, use a return flow catheter; first wash the pelvis gently with normal salt solution or sterile distilled water. Silver nitrate in solution, of a strength of $\frac{1}{10000}$, may be used.

S. B. Dudgeon and A. Ross, of London ("Annals of Surgery," March, 1910), recommend in colon infections the use of autogenous vaccine, and report a series of cures. A sterile urine was exceptional in chronic cases. Small doses of 100,000,000 to 200,000,000, administered every five days, were best. Relapses are apt to occur.

Perinephritis is an inflammation of the perinephric fatty tissue produced by cold, febrile disease, slight traumatism, or the spread of inflammation from another part.

The **symptoms** of this condition are rigidity of the spine, the inclination being toward the affected side, flexion of the thigh, pain in the loin and iliac region, and often pain in the knee. The symptoms resemble those of hip-joint disease in the second stage. Suppuration may or may not take place. In some suppurative cases the condition strongly suggests woody phlegmon (see page 136).

The **treatment** is wet cups to the loin, heat to the loin, rest, purgation by salines, morphin for pain, and, after the acute stage, potassium iodid internally. In a lingering case an incision should be made. It will frequently be followed by cure. Decapsulation has advocates. If suppuration occurs it is necessary to incise and drain.

Perinephric or Perirenal Abscesses.—An abscess in the perinephric fat is known as a perinephric or perirenal abscess. *Primary abscess* may follow a chill, may develop during or after an acute febrile disturbance, or may be caused by pus flowing from some other part, as the spine. Slight traumatisms, by producing hemorrhage, make the perinephric region a point of least resistance and lead to abscess. The causative injury may be produced by digging, stamping, coughing, falling, carrying a burden, lifting a weight, or riding on a horse or on a jolting wagon. *Consecutive abscess* is secondary to kidney inflammation, suppuration, calculus, tuberculosis, or cyst. In the consecutive form the symptoms may be masked by the malady to which perinephric abscess is secondary. As a rule, in a case of perinephric abscess there are found the constitutional symptoms of suppuration. There is high leukocytosis. The local symptoms are a deep aching and paroxysmal pain in the loin, intensified by lumbar pressure. There may be pain in the iliac region and pain in the knee. Edema of the corresponding foot and lameness are not unusual. The thigh is often drawn up. The spine is rigid and inclined toward the diseased side. Edema of the skin is usual, but fluctuation is not. An exploratory incision will settle a doubtful diagnosis.

The **treatment** is to lay open the abscess, wash it out, and drain.

Stricture of the Ureter.—This is usually at or near the termination of the ureter. It is due to gonococcic inflammation, pyogenic inflammation, or tuberculosis. The symptoms, as Howard Kelly says, are at first those of a vesical or renal inflammation. The diagnosis is made by the ureteral catheter. We may be unable to introduce it; we may introduce it with difficulty and find that the pelvis of the kidney is distended and that the urine obtained is slightly acid or even alkaline, much lower in urea than the urine from the other kidney, and perhaps contains pus. Stricture of the ureter causes hydronephrosis or pyonephrosis. Great care must be exercised in the examination of the ureter for stricture, and we know of cases diagnosticated as stricture that were simply spastic contractions or deviations in the course of the tube resembling stricture. Some urologists have regarded the condition as quite common, but we do not believe it is so; in several of the cases so diagnosticated a pyelographic study of the ureter has revealed tortuosities due to a descended kidney. These cases will often have greatly enlarged pelves and many of them suffer from mild attacks of kidney colic. Before arriving at a diagnosis the Blasucci catheter should be used and a pyelographic study be made.

Treatment.—Dilatation with bougies, resection of the diseased portion and anastomosis, resection of the diseased portion and implantation of the sound end into the bladder, or division of the stricture and suture. In tuberculosis the diseased kidney and ureter may be removed.

Hydronephrosis is a condition of the kidney resulting from an impediment to the outflow of urine by obstruction in the ureter, the bladder, or the urethra, the calices of the kidney becoming overdistended with urine and the glandular tissue being absorbed by pressure. It has been asserted by Albarran that secretion of urine ceases in a kidney whose ureter is completely blocked, distention being due purely to congestion. Hydronephrosis may be congenital, due usually to twisting of the ureter or to valve-formation obstructing the ureter at its point of junction with the pelvis of the kidney, the valve being produced because the ureter passes into the kidney pelvis at an unnatural angle. Occasionally imperforate urinary meatus produces hydronephrosis of both kidneys.

The **causes** of the acquired form are the pressure of pelvic growths or pregnancy, inflammation or tumor of the bladder, stone in the bladder, kidney, or ureter, twisting or kinking of the ureter of a movable kidney, enlargement of the prostate gland, and stricture of the urethra. Acquired hydronephrosis may involve both kidneys, all of one kidney, or only a part of a single gland.

Symptoms.—Hydronephrosis is most frequent in females. When a lumbar tumor is absent there may be no symptoms, or there may be pain in the back and abdomen, frequent micturition, a persistent or intermittent diminution in urine, or even occasional anuria. A mass may be found in the loin, which growth is dull on percussion and may come and go, a large urinary flow occasionally occurring as it disappears. Hydronephrosis may last a long while if only one kidney be involved, but death is not far distant if both glands suffer. Death occurs from uremia, from pressure on adjacent organs, or from rupture into the peritoneal cavity. The diagnosis is aided by the use of the cystoscope, by catheterizing the ureters, and by pyelographic study.

Treatment by aspiration may possibly cure, but the operation will have to be done repeatedly. Tapping on the left side is performed just below the last intercostal space; on the right side the tap is made midway between the last rib and the crest of the ilium. Some few cases have been cured by catheterizing the ureter (Pawlik). The proper operation in most cases is nephrotomy, stitching the edges of the cut kidney to the surface. After the kidney has been opened, explore the ureter by means of a uterine sound or an elastic bougie. A healthy ureter will permit the passage of an instrument of the size of from No. 9 to No. 12 of the French scale (Fenger). If the opening of the ureter into the pelvis cannot be found, open the pelvis or open the ureter. A valve should be slit longitudinally and sutured transversely (Fenger). If a permanent suppurating fistula ensues or if the organ is found extensively damaged, nephrectomy is to be performed, provided the other kidney is in reasonably good condition.

Pyonephrosis or **surgical kidney** is a condition in which the pelvis and the calices of the kidney are distended with pus or with pus and urine. The whole kidney may be destroyed. This condition has the same causes as hydronephrosis, for it is, in reality, usually an infected hydronephrosis. In some cases the inaugural malady is pyelitis, which causes blocking of a ureter. Watson, of Boston, has reported 2 cases associated with obliteration of the ureter by a mass of fibrous tissue (stricture of the ureter).

The **symptoms** are those due to the obstructing cause plus pyelitis. Pus may appear in the urine in incomplete obstruction, or it may intermittently come and go. Bacilluria and especially colon bacillus infection of the urine has a strong tendency, unless speedily controlled, to cause pyonephrosis. Constitutional symptoms of suppuration are soon manifest. A mass like the tumor of hydronephrosis may appear in the loin. If only one kidney is involved, and if the disease is due to blocking of a ureter,

recovery is to be expected. The diagnosis is rendered more certain by the use of the cystoscope and by catheterizing the ureters.

The **treatment** in the early stages comprises removal, if possible, of the cause of obstruction, and the employment of measures directed to the cure of the pyelitis. If obstruction is not complete, palliative measures may be employed for the tumor. If fever continues; if there is great visceral derangement; if pain is severe and constant, and if the mass continually enlarges, perform nephrotomy, stitching the organ to the surface if possible, or removing it if it is hopelessly disorganized and the other kidney is in a good or a fairly good condition.

Chronic Tuberculosis of the Kidney.—This condition may begin in one kidney, no other area of infection existing in the body. In such cases the bacteria were deposited from the blood. Even when the bacteria are deposited from the blood there is, in most cases, an initial focus of tuberculosis somewhere else in the body. Primary renal tuberculosis remains for a long time a local disease, but, unfortunately, the other kidney, sooner or later, is very apt to become involved, the process in the first kidney affecting the bladder and secondarily the other kidney. The important point is that tuberculosis of the kidney arising in this manner is at first a unilateral disease.

Tuberculosis of the kidney is seldom a primary disease and usually arises secondarily to tuberculosis of the prostate, bladder, or epididymis. In such a condition the kidney disease is always bilateral. Renal tuberculosis is particularly common in the third and fourth decades of life, and is more frequent in males than in females.

Symptoms.—Renal tuberculosis of arterial origin may exhibit no symptoms until the disease is far advanced. Renal tuberculosis secondary to disease of the bladder or prostate always presents symptoms.[1] A very common symptom of renal tuberculosis is the sudden onset of polyuria and frequent micturition. The patient is annoyed day and night, and in some cases micturition is distinctly painful. Paroxysms of renal pain are not unusual. The urine is acid and may contain pus or blood. Tubercle bacilli may be found in the urine or in the sediment of centrifuged urine, but they may be absent. Repeated examination should be made before it can be stated certainly that bacilli are absent. The presence of bacilli proves the diagnosis, but their absence does not negative it (Willy Meyer). If bacilli are not found, inject some of the urinary sediment into a guinea-pig, and note if tuberculosis arises in the animal. Czerny has shown that in cases of tuberculous kidney in which bacilli are not found in the urine the administration of tuberculin will cause great numbers to appear. This agent will also cause a marked febrile reaction if tuberculosis exists. The urine may or may not be albuminous.

In many cases the kidney is obviously enlarged, and the renal area is frequently tender and occasionally painful The patient loses flesh, and there is nocturnal fever followed by sweating. The use of the cystoscope furnishes important information. It shows from which ureter turbid urine is coming. Catheterization of the ureters should be practised by some one who is expert. Always examine carefully to determine if one or both kidneys are involved, if the bladder is diseased, and if the prostate gland or seminal vesicles are tuberculous.

Treatment.—Lumbar nephrectomy is not justifiable in the very beginning of a case, because such a patient may be cured by a combination of medical and hygienic treatment, and the weakening effect of the operation of nephrectomy may cause the other kidney to develop tuberculosis rapidly. Tell such a patient to lead an outdoor life. Brown recommends camp-life in the Adirondacks during the summer, and sends such patients south during

[1] F. Tilden Brown, "New York Med. Jour.," April 10, 1897.

the winter. If a patient cannot go to another climate, urge upon him the necessity of practically living out-of-doors (see page 230). Insist upon the taking of plenty of nutritious food. Full antituberculous treatment is indicated (see page 230).

If the kidney is markedly enlarged; if there is profuse hematuria; if the fever is high and persistent; if only one kidney is involved, and if the bladder and prostate are free from disease, perform nephrectomy. In cases with involvement of the other kidney or of the genito-urinary tract lower down, nephrectomy is not justifiable, although nephrotomy for drainage may, for a time, greatly benefit the patient.

Operations On the Kidney and Ureter.—Operation for Chronic Nephritis.—In 1897 Mr. Reginald Harrison advocated puncture of the kidney to relieve tension in cases of albuminuria, and in 1901 advocated incision of the true capsule of the kidney and puncture of the gland to accomplish the same purpose ("Brit. Med. Jour.," Oct. 19, 1901). Alexander Hugh Ferguson in March, 1899, reported 2 cases of interstitial nephritis cured symptomatically by decapsulation and multiple punctures ("Jour. Am. Med. Assoc.," March 11, 1899). Dr. Geo. M. Edebohls observed, between 1892 and 1897, that in certain cases of movable kidney with albuminuria the albumin and casts disappeared after nephropexy. Rose, Wolff, and Ferguson have observed the same fact. Harrison believes that renipuncture removes the symptoms by abating tension, but Edebohls concludes that nephropexy relieves the condition and possibly cures it by establishing vascular adhesions which carry on additional supply of blood. He proposed to operate for Bright's disease in 1899 ("Med. News," April 22, 1899). Edebohls deliberately operated for chronic nephritis and claimed 8 complete recoveries from chronic Bright's disease ("Med. Record," Dec. 21, 1901). There can be no doubt whatever that operation is sometimes followed by polyuria, disappearance of edema and other symptoms, and apparent cure. But in some cases the disappearance of symptoms has been too rapid to permit of the assumption that new vessels have caused it. In such cases it seems much more probable that relief of tension is the real curative factor. The capsule of the kidney is only slightly elastic, and tension may be brought about by an increase in the blood-supply, by edema, and by cell proliferation. Increased tension causes pain and perhaps hematuria, and tension is relieved by Harrison's plan of incising the capsule. Simple incision is easier, safer, and probably just as useful as stripping the capsule off of the kidney. Edebohls advocates decapsulation and says that the polyuria begins about the tenth day after operation; that improvement begins in one month and is gradual; that the cure is due to vascular adhesions; that the adhesions contain more arteries than veins; that the free blood-supply absorbs exudate and products of inflammation, frees the tubes and glomeruli from pressure and constriction, causes the reëstablishment of a normal circulation and the regeneration of epithelium (Ibid.).

The exact status of the operation is not as yet determined. It does, however, seem to be proved that operation is in some cases followed by apparent cure or great amelioration of the condition. Whether permanent cure is ever thus obtained is doubtful, and the part played by rest in bed and drugs in effecting an improvement must not be lost sight of. I have seen no case of genuine cure. Albumin has always continued present in the urine. It is certain that the operation is unjustifiable unless medical treatment has been tried and failed, unless the symptoms are growing worse, and unless they indicate danger. James Tyson ("Med. Record," July 8, 1911) sets forth dangerous symptoms as follows: Persistent dropsy, uremia (violent headache, convulsions, or coma), excessive amount of albumin causing anemia and weakness, anuria. The best results are obtained in chronic parenchy-

matous nephritis associated with marked anasarca. Pain and bloody urine are often much improved by incising the capsule. Postoperative suppression and the anuria of acute infectious diseases may be favorably influenced by the operation. In perinephritis it may prove curative. An important fact which Rovsing maintains and Edebohls proves is that chronic nephritis may be for some time a unilateral disease. (Read the views of Schmidt, in "Med. Record," Sept. 13, 1902; of Rovsing, of Copenhagen, in "Mittheilungen aus den Grenzegebieten der Medicin und Chirurgie," vol. x, 1902, and editorial in "Jour. Am. Med. Assoc.," Jan. 11, 1902; James Tyson, in "Trans. of Amer. Physicians," 1911, and "Med. Record," July 8, 1911.) Personally, I would not operate in the presence of grave and advanced cardiovascular disease. Tyson believes that albuminuric retinitis, very irregular heart, and valvular disease forbid operation, and that in patients over fifty the operation is of slight value.

The operation as practised by Edebohls may be done on both kidneys either at one sitting or in two séances. In some cases only one kidney is subjected to operation. Edebohls takes a very radical view and would operate on any case free from incurable complications, if an anesthetic can be given and if the life-expectancy without operation is not less than one month ("Med. Record," Dec. 21, 1901). Ether is given or nitrous oxid and oxygen. Lay the patient prone with an air-cushion under the belly and expose the kidney by a vertical incision at the edge of the erector spinæ mass, which cut does not open the sheath of the muscle. Remove the fatty capsule from the true capsule, continuing the dissection around each pole until the pelvis of the kidney is reached. The kidney is extruded from the wound, the true capsule is incised along the convex border and around each pole, is separated from the kidney, and is cut away close to its junction with the kidney pelvis. The kidney is then returned to its bed of fat and the wound is closed (Ibid.). Edebohls does not drain unless there is considerable edema. He reported 18 operations without a death. In 9 of the cases the operation was done more than one year ago, and 8 of them are said to be cured. Personally, I do not believe that the operation can really cure Bright's disease. It cannot restore altered connective tissue and epithelial cells. The new blood-supply must be through scar tissue, and we have yet to learn that such a blood-supply can be efficient. The operation should be restricted to acute nephritis, to acute exacerbations in chronic cases, to conditions with severe renal pain, hematuria, anasarca, very high albumin percentage, or persistent and notable diminution in the amount of urine voided (Ertzbischoff, in "Archiv. générales de Chirurgie," April, 1908).

Nephrotomy means incision of a kidney, but the term is sometimes, though wrongly, applied to the exploratory exposure of the kidney without incision of the organ. When the kidney wound is left open, as it almost invariably is, the operation should be called *nephrostomy*. The operation is employed to evacuate infectious material, relieve tension, permit of the removal of a calculus or exploration of the ureter, and for diagnosis of renal disease. The patient lies upon the sound side, a sand-pillow or a cylindrical air-bag being placed under the flank. The *incision* is made ½ inch below the last rib and close to the outer border of the erector spinæ mass, and runs obliquely downward and forward toward the iliac crest for 3 inches, the incision being enlarged later if required. Divide the skin, the superficial fascia, the fat, the external oblique, the posterior border of the internal oblique, and the outer edge of the latissimus dorsi. This incision exposes the lumbar fascia. Push aside the last dorsal nerve and incise the lumbar fascia, when the perirenal fat will bulge into the wound. Two distinct layers of fat exist. Tear through this fat with dissecting forceps to expose the kidney, which can now be opened while it is forced into the wound

by the hand of an assistant making abdominal pressure. In some cases the kidney can be brought out of the wound for exploration and operation. In others it cannot. When it cannot be drawn out it is brought into the wound and supported by means of a pad of gauze under each pole.

Kocher's incision for nephrotomy is begun in the angle between the sacro-lumbalis muscle and the twelfth rib, and is carried downward, forward, and outward to the axillary line (see Fig. 248). This incision divides the skin, subcutaneous tissues, lumbar fascia, the latissimus dorsi, and the serratus posticus inferior muscles. If possible, the kidney is brought out of the wound.

Edebohls's method enables the surgeon to explore the kidney thoroughly because this organ is brought outside of the body. It is not suited to cases in which the organ is much enlarged or when it has a short pedicle. Its best field is in operations for movable kidney. The patient lies prone, with a large cylindrical inflated rubber pad beneath his abdomen. A vertical incision is made close to the border of the erector spinæ muscle, from just below the last rib to just above the iliac crest. The sheath of the muscle is not opened. The fibers of the latissimus dorsi are separated by blunt dissection. The iliohypogastric nerve is found and retracted. The transversalis fascia is incised and the fatty capsule reached. The two layers of the fatty capsule are torn through and the kidney exposed. The fatty capsule is *well separated* from the kidney front and back. The patient is pulled by the legs toward the foot of the table, the pad remaining stationary. This change of position brings the pad beneath the chest, abdominal respiration takes place, the kidney is forced into the wound, and can be easily withdrawn and thoroughly examined. In many cases the lumbar incision does not expose the kidney pedicle completely enough to make the surgeon feel that he can readily clamp it should nephrectomy become necessary, and in any operation upon the kidney nephrectomy may at any minute become necessary. Cutting the twelfth rib adds to the exposure, but in cutting it the pleura may be opened. Wm. J. Mayo ("Annals of Surgery," Jan., 1912) in 203 lumbar operations divided the twelfth rib 51 times, and in 13 of the operations accidentally opened the pleural cavity. In not a case did the lung collapse (probably because the patients lay upon the abdomen with the hips somewhat elevated, the chest being fixed by the position). In each case the torn pleura was sutured, the stitches including tissue of the diaphragm.

Mayo discovered that after division of the quadratus lumborum muscle and the lateral arcuate ligament (which binds the twelfth rib to the transverse process of the first lumbar vertebra) the rib can be lifted out of the way and does not need to be divided. Mayo now operates as follows: Beginning over the eleventh rib $2\frac{1}{2}$ inches external to the spines of the dorsal vertebræ make a longitudinal incision 3 inches in length. From this point carry the incision downward and forward along the anterior margin of the quadratus lumborum to 1 inch above the crest of the ilium; it is then carried forward parallel to the crest. The twelfth rib is cleared nearly to its articulation; the pleura is pushed up out of the way. The erector spinæ mass is retracted toward the spine. The costal margin is raised by retraction. A wide area for operation is exposed, the kidney can be brought out of the wound, and the pedicle can be seen and reached.

A common method of opening the kidney is to make a longitudinal incision through its convexity sufficiently large to admit the finger into the renal pelvis. This incision may be enlarged if necessary until the kidney is split in half. When the operation is completed close the kidney wound completely by means of a round needle and catgut, unless drainage is necessary or packing is required. Another popular incision is placed longitudinally a little posterior to the convex border. This goes through the bloodless zone of Hyrtl, and causes less hemorrhage than the incision along the convexity. Marwedel's incision is a

transverse cut at the middle of the convex border of the kidney into the renal pelvis. It is doubtful if this incision is accompanied by less bleeding than longitudinal incision of the convexity. After the completion of our work on the kidney the lumbar wound is closed completely or is partially closed to permit of drainage.

Operation for Stone in the Kidney By Pyelotomy or Nephrotomy (Pyelolithotomy, Nephrolithotomy).—It used to be held that incision of the pelvis of the kidney is far more apt to be followed by fistula than incision of the substance of the kidney. The Mayos, Bevan, and others have proved that this conviction is untrue. In many cases of stone pyelotomy is preferred to nephrotomy. It is used for single stones of moderate size in the pelvis and unaccompanied by suppuration. When we have a large branched stone, coral-shaped stones, multiple stones, and stones accompanied by distinct and gross evidences of infection, then nephrotomy should be preferred to pyelotomy (Bevan and Smith, in paper read before the American Surg. Assoc. in 1908). In both operations the patient is placed on the sound side with a sand-pillow or cylindrical air-bag under the flank. In both cases the incision recommended for nephrotomy is used. In both cases the kidney is lifted into the wound or brought out of the wound so that it may be satisfactorily palpated. In both cases bleeding is controlled by having an assistant, if possible, grasp the pedicle with his fingers or with a pair of forceps, each blade of which is covered with a bit of rubber tube, while the surgeon opens the pelvis or the kidney tissue, removes the stone, and explores with the finger.

Pyelolithotomy.—Remove the fat from the posterior surface of the pelvis of the kidney. We may then be sure that no aberrant vessel is in our way. The normal vessels are all in front of the pelvis. The posterior wall of the pelvis is now opened, the stone is extracted, the pelvis explored, the cut in the pelvis is sutured with fine catgut sutures, the kidney is restored to place, a cigarette drain is introduced, and the wound in the loin is closed.

Nephrolithotomy.—The methods of incision, exposure, and opening the kidney are described on page 1292, under Nephrotomy. When the kidney has been opened, loosen the calculus with the nail, and remove it with the finger, with a scoop, or with forceps. After removing the stone, suture the incision with catgut, and release the pressure on the pedicle. Hemorrhage will usually be controlled, but sometimes violent bleeding occurs. If in spite of this plan bleeding occurs, take out the stitches and apply pressure and hot water, compress the bleeding points by suture-ligatures, and close again by Stellwagen's stitches (see Figs. 853, 854). In some cases plug with iodoform gauze, suturing the gauze in place within the kidney by fine catgut and leaving it until it loosens. When hemorrhage ceases, put a large drainage-tube down to the kidney. Close the wound in the muscles and integument and dress antiseptically. The dressings must be changed frequently and the tube should be shortened daily. In some cases nephrectomy is necessary (see page 1285). Formerly in these cases I always drained for a time and removed the kidney secondarily, believing that the patient would gain strength in the interval and stand the severe operation of nephrectomy better. I am satisfied that in most cases this view is wrong, because removal of a kidney bound down by adhesions is one of the most perilous and difficult operations of surgery.

Nephrectomy is the removal of a kidney. There are two methods of nephrectomy—the *lumbar* and the *abdominal*. The first nephrectomy (according to Watson) was performed in 1861 by an American, Walcott. The operation was transperitoneal and was for the removal of a cancerous kidney. Simon, in 1869, performed the first lumbar nephrectomy and the first successful nephrectomy. Before performing nephrectomy ascertain the competence of the kidneys. If at least 1 per cent. of urea is not being excreted, it is very un-

safe to operate. Be sure the patient possesses two kidneys. Examination of the bladder by the cystoscope will show the ureteral orifices, a strong indication that both kidneys are present. Nevertheless, when we reflect that a horsehoe kidney has two ureters, the proof is not absolute. Catheterization of the ureters is advisable if it can be performed, but it will probably require a specialist to perform it. Proof absolute of the presence of two kidneys consists in feeling both of them. If in doubt as to the question, and if uncertain as to the ability of the organ which is to be left, feel each kidney during the operation and before removing either, or perform a preliminary exploratory laparotomy.

Lumbar Nephrectomy.—The patient is placed on the sound side and a pillow is placed under the loin. Several incisions have been proposed. In many cases the oblique incision is first made to permit of exploration. This incision is begun $\frac{1}{2}$ inch below the last rib and by the edge of the erector spinæ muscle, and is carried downward and forward toward the iliac crest. In some cases a kidney can be removed through this cut. In other cases the cut must be enlarged. It can be enlarged by extending the cut downward. Morris enlarges it by adding to it a vertical incision, which begins 1 inch below the origin of the oblique cut. König's incision for nephrectomy consists of a vertical cut by the edge of the erector spinæ, carried almost to the iliac crest, from which point it is curved forward toward the umbilicus, and is carried to or even through the rectus muscle. After thorough exposure lift the kidney and separate it from the peritoneum, if possible, with the finger; clamp the pedicle; pass an armed aneurysm needle between the vessels of the pedicle; ligate in two places; cut between the threads, and arrest hemorrhage permanently by ligation of each vessel. If the ureter be healthy, ligate it with silk and drop it back; if it be foul and purulent, scrape it with a sharp spoon, wash it with corrosive sublimate, and touch it with pure carbolic acid, and then either ligate it with catgut and drop it back or sew it into the wound. If hemorrhage persists from the wound, plug with gauze. Insert a drainage-tube and close the wound. If the peritoneum be accidentally opened, close it with Lembert sutures. Kocher's method is excellent, and enables the surgeon to feel the opposite kidney before removing the one which is known to be diseased. The incision is begun as described on page 1293, and is carried forward so as to expose the reflection of the peritoneum on to the colon in the posterior axillary line (see Fig. 248).[1] At this point the peritoneum is opened, and the surgeon's hand is inserted into the abdominal cavity and feels the other kidney. If another kidney exists and it is found to be healthy, the diseased organ may be removed. Brewer's personal statistics show 53 cases of nephrectomy with 2 deaths, a mortality of 3.8 per cent. ("Med. Record," March 20, 1909).

Abdominal nephrectomy is more dangerous than the lumbar operation. The position is supine. The incision is that of Langenbeck—4 inches in length in the linea semilunaris, its center corresponding to the umbilicus. Open the abdomen, introduce a hand, feel the kidneys, and if both show serious disease, do not perform nephrectomy. If we decide to remove one kidney, keep the small intestine away by pads, push the colon toward the umbilicus, incise the outer layer of the mesocolon, and bare the kidney. Strip off the peritoneum from the kidney and its vessels, and ligate the vessels by passing strong silk through the center of the pedicle with an aneurysm needle. Ligate the ureter if healthy, and divide it. If the ureter is septic, fasten it to an opening made in the loin by cutting on to forceps pushed to the outer edge of the quadratus lumborum. Stop bleeding, irrigate the belly cavity, and dress as usual, employing drainage only when septic matter has passed into the peritoneal cavity or when oozing of blood is persistent.

[1] Kocher's "Text-Book of Operative Surgery."

Nephrectomy in Children.—The operation is proper in certain non-malignant troubles. Jepson did a successful nephrectomy for a congenital cystic kidney on a patient four months and fourteen days of age. Rovsing did it successfully for congenital hydronephrosis, the patient being nine months old. Roswell Park did a successful nephrectomy for congenital cystic kidney on a child twenty-three months of age. The value of nephrectomy for sarcoma is certainly doubtful. The operation never really cures, and if an operative recovery is obtained the disease appears after a time in the other kidney. Jessup performed nephrectomy in 11 children and every case died within two and one-half years of the operation. The operation often prolongs life and relieves discomfort, but does not cure.

Partial Nephrectomy.—This operation may be performed in some cases for wounds, cysts, and innocent tumors. After removing the damaged or diseased part, bleeding points are ligated with catgut. The wound surfaces are approximated as well as possible by catgut sutures. Drainage is intro-

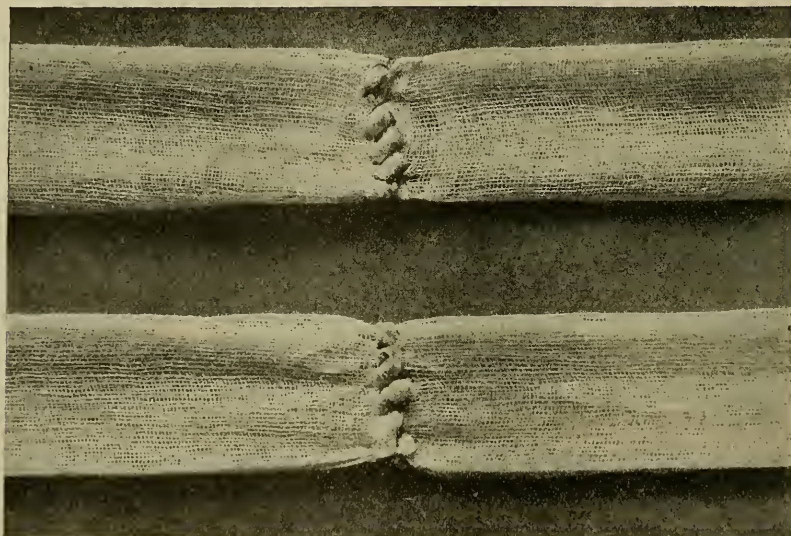

Fig. 856.—Gauze slings, each composed of two pieces sutured together with fine plain catgut.

duced. The value of partial nephrectomy in some cases seems certain, and we should apply it when possible instead of the complete operation,[1] except in cases of malignant disease.

Renipuncture.—This is an operation devised by Reginald Harrison for the relief of albuminuria due to elevated tension. The kidney is exposed in the loin, the capsule is incised, and punctures are made in the kidney. Simple incision of the capsule will usually relieve nephralgia. (See Operation for Chronic Nephritis, page 1291).

Nephropexy is fixation of a movable kidney. The term "nephrorrhaphy," so long used for the operation, really means suturing a wound in the kidney.

The Author's Modification of the Elder Senn's Operation.—Many surgeons feel that it is not desirable to pass sutures through the kidney substance, and I have entirely abandoned the use of them in operations for movable kidney. Urinary fistula has followed suturing. Again, the value of such sutures

[1] See Oscar Bloch, in "Brit. Med. Jour.," Oct. 17, 1896; also reports of Czerny, Bardenheuer, Tuffier, and Kümmell.

is very doubtful. The kidney is a very soft organ, and if it is suspended by sutures, they are certain to cut out. In most suture operations the kidney when restored to place is not placed sufficiently high and has its ureter and vessels looking forward; in other words, there is a one-fourth twist in the ureter. In operations like Goelet's and Kelly's, which raise the kidney much nearer its proper level and which do not twist the ureter and renal vessels, the upper pole is not anchored and tends to tilt forward (see page 1279). The operation herein described fixes the kidney without using sutures.

The patient lies upon his abdomen, Edebohls's bag being placed directly beneath the lower abdomen. A vertical or slightly oblique lumbar incision is made, the perirenal fat is exposed, and its two layers are torn through until the kidney is reached. The fatty capsule is thoroughly stripped from the entire organ. The kidney is brought out of the wound. This is accomplished by pulling the patient toward the foot of the bed, so that the pad gets under the ribs, when traction on the fibrofatty capsule will cause the kidney to emerge from the wound. The posterior fatty capsule is cut away, and also the anterior fatty capsule up to the hilum. The true capsule of

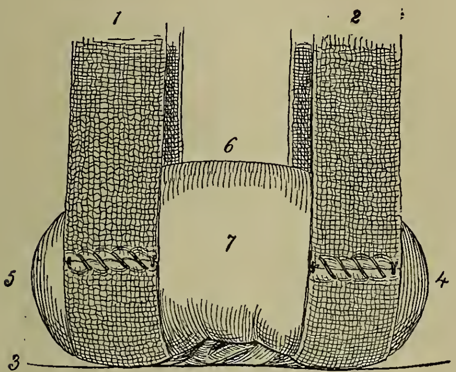

Fig. 857.—Right kidney projecting from wound. Observer standing on right side of patient: 1 and 2, Slings in place, with sutures external; 3, skin of the back; 4, upper renal pole; 5, lower renal pole; 6, convex border of kidney; 7, external surface of kindey. (Slings should be broader than those shown in illustration.)

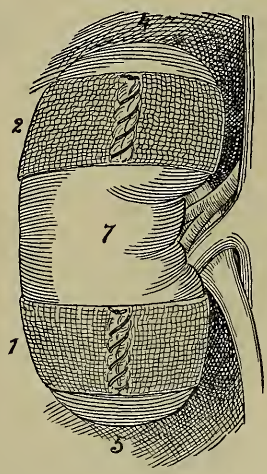

Fig. 858.—Right kidney restored to place, seen from in front: 1 and 2, Slings in place, sutures anterior; 4, upper renal pole; 5, lower renal pole; 7, anterior surface of kidney. (Slings should be broader than those shown in illustration.)

the kidney is scarified. I always have packing prepared by suturing together with the finest plain catgut the ends of two pieces of iodoform gauze. Two such strands are prepared (Fig. 856). One piece of iodoform gauze is placed under the upper end of the kidney, and another piece under the lower end, the sling in each instance being directly under the kidney with the suture line external and not in front, as the kidney protrudes from the wound in the back (Fig. 857). When the kidney is replaced the suture line will lie in front (Fig. 858). The kidney is replaced and will then lie in a sling composed of two pieces of gauze, the ends of which protrude from the wound. Another piece is placed below the lower renal pole to fill up the space which always exists there and to stimulate granulation. This space below the kidney is a frequent cause of subsequent loosening in most suture operations, because the kidney hangs in it unsupported, as a bucket hangs in a well. Harris recognizes this, and in his operation closes the space by sutures. Gauze is packed in over and about the kidney, and over this the two long slings

82

are tied. Several sutures of silkworm-gut are inserted to close the superficial parts and the lumbar aponeurosis; some are tied and some are left untied. A large gauze pad is placed upon the abdomen over the anterior surface of the kidney, and the lumbar wound is dressed with gauze. The dressing and gauze pad are held in place by a binder. In about eight or ten days the gauze should be soaked with dripping salt solution during half an hour and the packing removed. At this time the catgut is destroyed and the gauze can be easily pulled out. The tied sutures are cut and removed, the sutures left unfastened are tied, and a small piece of gauze is inserted as a drain between the granulating surfaces. If a continuous piece of gauze was used, ether must be given before removal is attempted. Further, in the old operation, a large wound was left to granulate and weeks were often required to obtain healing. In this operation the wound is usually entirely healed in from eighteen to twenty-one days. After the performance of nephropexy the patient remains

Fig. 859.—Gibson's incision for operations on the lower ureter. The superficial incision (C. L. Gibson).

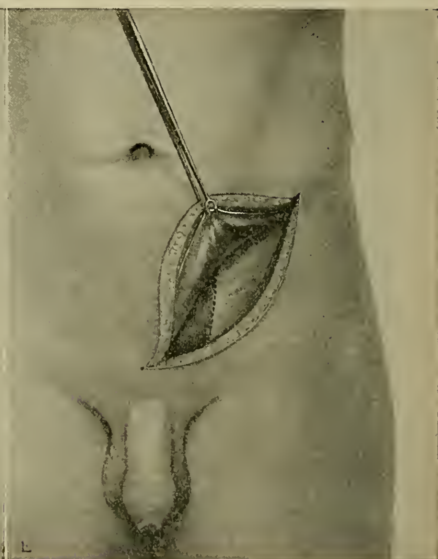

Fig. 860.—Gibson's incision for operations on the lower ureter. The upper flap, consisting of skin, external and internal oblique muscles, is retracted. The dotted line represents the line of incision in the transversalis fascia (C. L. Gibson).

in bed for three weeks. By this operation the kidney is placed in a proper situation, is surrounded with granulations which are converted into scar-tissue, and the organ becomes encased in a box of fibrous tissue. I believe that a kidney so treated will probably remain fixed.

If a kidney has been decapsulated, gauze slings should not be placed around it, because removal of them might lacerate the kidney. After decapsulation the surgeon rests content when he has filled the space below the kidney with a support of gauze.

Ureterolithotomy.—If the stone is impacted in the upper two-thirds or three-fourths of the tube it may be reached by an incision from the twelfth rib downward and forward to just anterior to the anterosuperior spine of the ilium and then parallel to Poupart's ligament until above its middle. The peritoneum is stripped up as in extraperitoneal ligation of the iliac vessels. The ureter adheres to the peritoneum. The operation is strictly extraperitoneal.

Gibson's incision for operations on the lower ureter ("Amer. Jour. Med. Sciences," Jan., 1910) is the most useful for reaching and amply exposing the lower ureter. Further, it enables us to feel and accurately operate upon the tube, the entire operation being extraperitoneal. Gibson thus describes his operation:

"The skin incision runs from the midline about a finger's breadth above the pubes, horizontally outward nearly parallel to Poupart's ligament at first (Fig. 859), and curves rather sharply upward at its midpoint to end about opposite the anterior superior spine of the ilium. This incision is deepened in the same line through the aponeurosis of the external oblique and the internal oblique muscle—the latter is the only structure which suffers any real damage, and only to a slight degree, for the lower part of the incision runs about parallel to its fibers, only the ascending leg cuts across a small part of these fibers. The incision stops short of the transversalis, which is not dis-

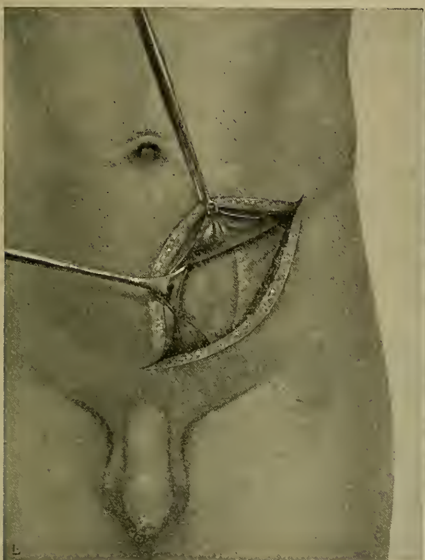

Fig. 861.—Gibson's incision for operations on the lower ureter. The edge of the rectus muscle is strongly retracted inward; between it and the cut edge of the transversalis fascia the peritoneum is exposed (C. L. Gibson).

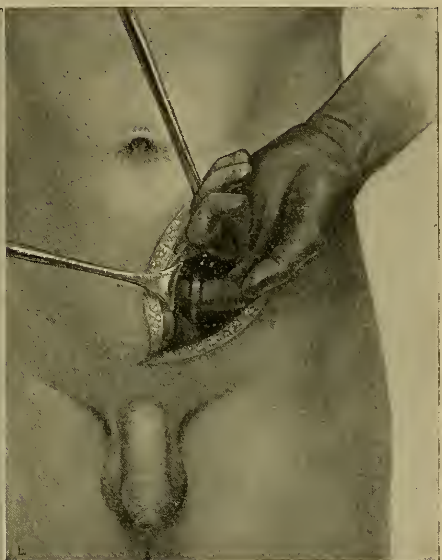

Fig. 862.—Gibson's incision for operations on the lower ureter. The peritoneum has been pushed upward. The ureter is lifted out of the pelvis and brought to the level of the external wound (C. L. Gibson).

turbed at all. With efficient retraction of the upper flap the external border of the rectus muscle is identified (Fig. 860) and the *fascia* of the transversalis is now divided by a vertical incision close to and parallel to the rectus—that is, at *right angles* to the original incision. Two retractors are now inserted, the outer one retracts the cut edge of the transversalis outward, the other (Fig. 861) pulls the rectus muscle well toward the midline. A generous space is thus obtained, situated well toward the midline (the lower part of the ureter is practically in the midline and difficult of access by other extra-peritoneal exposures). The floor of this space is occupied by the peritoneum. The patient being in a complete Trendelenburg position, the peritoneum is easily and gently pushed away, and a free access to the pelvis is secured. So ample is the space and view that the whole hand can be introduced under the control of the eye. The ureter is released from its surroundings and easily brought to the level of the wound" (Fig. 862).

When the tube has been exposed it is opened by a longitudinal incision. The stone is removed. The ureter is explored by means of a sound to see if it is free. After removing the stone, close the wound in the ureter with sutures of very fine chromic gut. Deep sutures pass through all the coats and are tied. Over this a layer of superficial sutures are inserted. Close the tissues about the ureter and drain by rubber tissue. Never drain by gauze. To do so will cause a urinary fistula. In a woman a stone near the vesical opening can be reached by a vaginal incision. Stone in the vesical portion of the ureter may perhaps be removed by aid of an operating cystoscope or by forceps after the performance of a suprapubic cystotomy.

My colleague, Prof. John H. Gibbon, advocates a combined intra- and extraperitoneal route for stones anywhere in the lower two-thirds of the ureter. The peritoneal incision permits of exploration and exact localization of the stone, allows the surgeon to push the calculus from an inaccessible into an easily reachable position, and makes the removal vastly easier. The stone is removed by extraperitoneal incision of the ureter, and the peritoneum is closed (Gibbon, in "Annals of Surg., Gynec., and Obstet.," May, 1908).

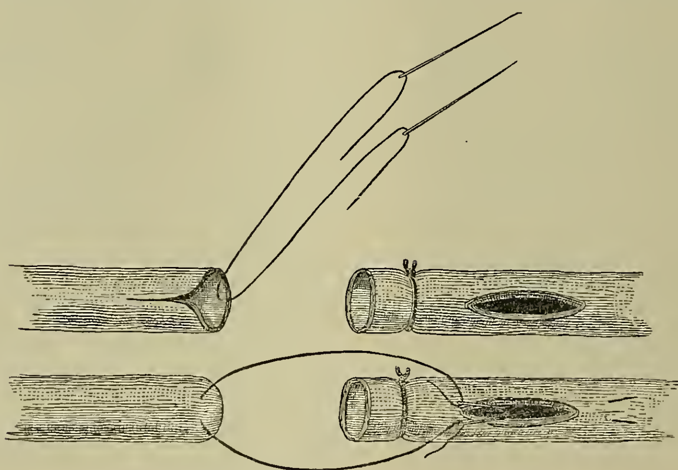

Fig. 863.—Van Hook's method of ureteral anastomosis.

Uretero-ureterostomy (*Van Hook's Operation*).—In this operation ligate the lower end of the divided ureter with silk or catgut. About ¼ inch below the ligature make an incision in the long axis of the tube. This incision is in length equal to twice the diameter of the tube. Each end of a piece of fine catgut is threaded to a fine needle. This thread is passed through the upper end of the ureter (Fig. 863). The needles are made to enter the lower end of the tube through the door made by the surgeon. They are pushed through the wall of the ureter ½ inch below the door (Fig. 863). Traction upon the strings causes invagination, and the ligature ends are tied. If the operation is intraperitoneal the ureter is wrapped about with peritoneum.

Intestinal Implantation of the Ureters.—This operation may be employed in exstrophy of the bladder and in vesical cancer in which it is necessary to remove the bladder. After this operation there is danger of infection of the ureters and consequent ascending ureteritis and pyelonephritis, and the presence of urine in the bowel usually causes inflammation of the rectum and incontinence of urine may take place.

Maydl asserts that a piece of the bas-fond should be removed with the ureter, and implanted with it into the intestine, the flange hanging free in

the lumen of the gut. If this is done, the relations of the ureter to the muscular coat of the bladder are not interfered with, stricture is less likely to occur, ascending infection is antagonized, and suppurative conditions arise at the margin of the flange rather than, as in other methods, directly in the cut ureter. Maydl has collected the records of 14 cases operated upon by this method, with 2 deaths.[1] I performed it twice, with 1 death. In vesical exstrophy Peterson transplants a vesical flap containing both ureteral orifices into the descending colon.

Cystoscopy is the employment of the cystoscope for the study of the interior of the bladder, the prostate, the ureteral orifices, and the appearance of the fluid coming from each kidney.

The cystoscope is an instrument of great value in the hands of a skilful and experienced man, but is practically useless when employed by a novice. All of my cystoscopic examinations are made for me by Dr. Stellwagen or some other expert. In using a cystoscope the mucous membrane may be burned with a hot lamp. This causes inflammation, and if an eschar forms, it will be cast off, exposing a granulating surface. Schmidt calls attention to this injury, speaks of the condition as *ulcer cystoscopicum*, says it is in the fundus, has the shape of the instrument, and heals in from fourteen to twenty-one days ("Jour. Amer. Med. Assoc.," July 19, 1902).

Cystoscopic examination of the bladder owes its present position to Messrs. Max Nitze and Joseph Leiter, who were the first to introduce practical instruments: Nitze in 1876 and Leiter in 1879. The great obstacle in former years was the danger of burning the mucous membrane by overheating of the lamp. The invention of the cold lamp by E. C. Preston eliminated that danger, and was a great step forward. Nitze was the first to recognize the futility of examination by reflected light and constructed an instrument with the light on the end which to-day is copied by all of the modern instruments.

Cystoscopes may be divided into several types: (1) The examining instrument; (2) the instrument carrying ureteral catheters or the catheterizing cystoscope; (3) the operating cystoscope. They all have certain mechanical features in common, but differ in their construction and lens arrangement.

The examining instruments are of two fundamental types—the direct and the indirect. In the direct there is a straight telescope with a series of wide angle lens that give the picture of the bladder in front and slightly to the side. In the indirect the lens is so ground and set as to enable the operator to look toward the prostate.

Catheterizing cystoscopes are also of two kinds—the direct catheterizing and the indirect. In the direct catheterizing cystoscope the catheters are passed directly from the carrying tubes into the ureters. In the indirect catheterizing cystoscope the catheter is bent or directed by a lever on the end of the instrument operated by a thumb-screw on the penile end. By raising or lowering the lever the angle of the catheter is altered to facilitate its introduction into the ureteral orifice.

It is obvious that the bladder should be distended in order to permit of cystoscopic examination. For this purpose air and water have been utilized. The modern tendency is in favor of water distention. Some of the operating instruments, notably that of Prof. Lewis, require air.

Water as a dilating medium is superior to air, unless operative work is to be done through the instrument, in which case the inevitable hemorrhage precludes the use of water. The air instruments show but a small field, the distention causes pain and is often followed by mild cystitis.

From the foregoing it is plain that one type of instrument is not suited to all cases, and each has its claim to practical utility. Some cases can be most

[1] Editorial in "Jour. Amer. Med. Assoc.," May 6, 1899.

readily catheterized by the direct, while others are only reached by the indirect, plan. It is my conviction that if the ureteral orifices are normally placed, the direct method is quicker and more readily learned by the beginner. Men who have had training had best use the A. C. M. I. cystoscope (Figs. 864, 865). It is an indirect or oblique cystoscope, but has a corrected image field which enables the operator to work as he sees and not the reverse (as is necessary with the uncorrected image field). These new instruments cause less pain than direct instruments, and give a very wide field. When from any cause the ureteral orifice turns backward (which only happens in a very small percentage of cases) the indirect cystoscope is indispensable, it being practically impossible to reach the ureteral orifice by the direct instrument.

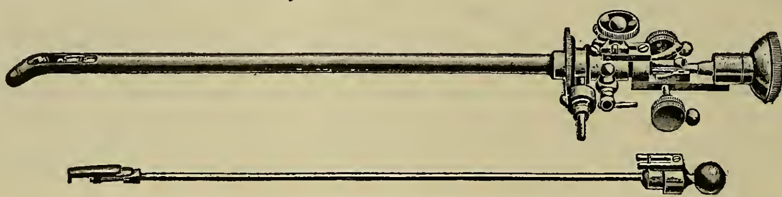

Fig. 864.—The A. C. M. I. double catheterizing cystoscope.

There are at present many different forms of cystoscopes on the market, notable among them are the Nitze, Casper, Tilden Brown, Cabot's modification of the Tilden Brown, Buerger, Albarran, Bransford Lewis, and the so-called Universal. The universal instruments of Bransford Lewis and Tilden Brown possess features of great practical utility.

Sterilization of Cystoscopes and Ureteral Catheters.—In order to sterilize the cystoscope before using, place it for five minutes in a solution of mercury oxycyanid (1:1000) or formaldehyd (1:500). The sterilizing power of formaldehyd gas is not to be relied on. Some operators use a 5 per cent. solution of phenol, in which the instrument is immersed for twenty-four hours, after which it is dipped into glycerin, which both neutralizes the phenol and lubricates the

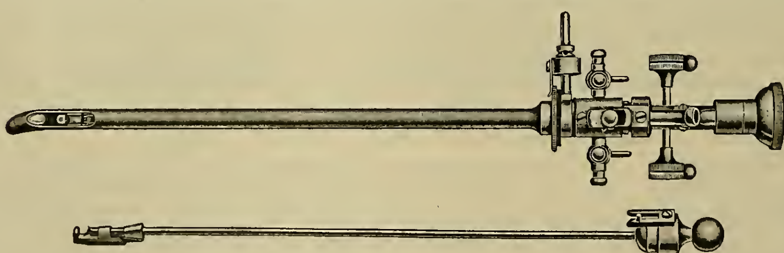

Fig. 865.—The A. C. M. I. operating cystoscope.

tube. The mercury oxycyanid solution is easily used and is thoroughly satisfactory. Should formaldehyd solution or formalin gas be used, always wash the instrument thoroughly with salt solution before using to prevent irritation by the sterilizing medium.

Dr. M. P. Willard, of San Francisco, in "Jour. Amer. Med. Assoc.," October 4, 1913, advocates the following method for sterilizing ureteral catheters: The ureteral catheter is placed in a muslin bag 2 cm. wide by 75 cm. long. The bag is enclosed, with the catheter in it, in paraffin paper, and secured by encircling strips of adhesive plaster. As many may be prepared as is thought necessary. The package is placed for twenty minutes in an autoclave with a pressure of 8 to 10 pounds. When the catheter is to be used the paper is removed and the end of the instrument is exposed by pulling back the linen bag and the

tip of the catheter is engaged in the carrying tube of the cystoscope. As the catheter is fed through the cystoscope the linen bag is pulled back; in this way the fingers do not come in contact with the catheter.

Ureteral catheters can be sterilized by placing them in an open shallow dish containing a saturated solution of ammonium sulphate or sodium chlorid and boiling them for five or ten minutes. The following precautions must be observed: Each catheter should be wrapped in gauze and the bottom of the pan covered with gauze. If the catheters are allowed to touch each other or curl upon themselves the shellac coating will melt and ruin the instruments. They may also be sterilized in the same manner as the cystoscope, care being taken if formalin was used to carefully wash away the germicide, especially from the lumen of the catheter.

Fig. 866.—Different types of ureteral catheters: *a*, Blasucci; *b*, return flow for irrigation; *c*, Garceau; *d*, another type of Blasucci; *e*, Cunningham; *f*, olivary tipped; *g*, *x*-ray whistle tip.

Contra-indications to Cystoscopy.—The bladder must hold at the very least 50 c.c. of fluid. If it holds less cystoscopy is useless. Examination is either impossible or unsatisfactory if the prostate is greatly enlarged. Contracted meatus urinarius and stricture of less caliber than No. 24 of the French scale are correctible contra-indications. Papillomata and other tumors and foreign bodies of the urethra are impediments. In acute Bright's disease instrumentation is dangerous, because it may be followed by suppression of urine. The following are further contra-indications, as suggested by Follen Cabot and Henry G. Spooner, in "Med. Record," July 11, 1903: When it is obvious that operative intervention would be useless; when there is a large tumor; in acute cystitis; in tuberculosis in which the diagnosis is evident without the cystoscope. In women, pelvic adhesions and large exudates may interfere with cystoscopy.

Technic of Cystoscopy.—The patient should, if possible, be carefully sounded once a day for several days previous to the cystoscopic examination; this establishes tolerance of the urethra. He should be placed upon a suitable table, such as that devised by Tilden Brown or Bransford Lewis, as shown in Fig. 868.

The urethra is cleaned by irrigation with salt solution. General anesthesia is rarely necessary provided the operator is gentle in his manipulations.

There are, however, some hypersensitive urethras which it is necessary to anesthetize. Cocainization of the urethra will usually be efficient. This is carried out by instillation through the Keyes-Ultzmann syringe or, better, through a soft-rubber catheter into the posterior portion of the canal of

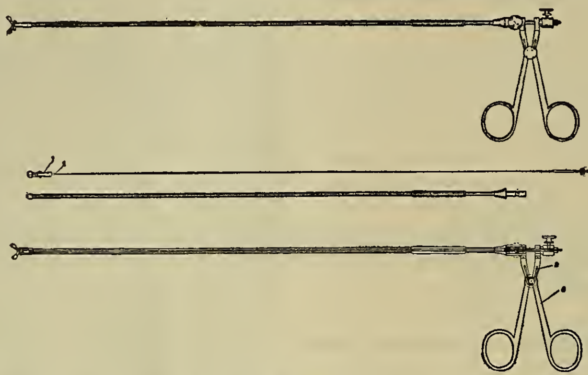

Fig. 867.—Buerger's rongeur forceps with flexible shank for use with Buerger's operating cystoscope.

1 dram of a 4 per cent. solution of cocain. Alypin, placed in the canal at the points of greatest tenderness by means of Dr. Lewis's repositor, answers very well. These tablets are allowed to dissolve in the urethral mucus. The points of greatest tenderness are the fossa navicularis, the bulbo membranous junction, and the prostatic urethra about the verumontanum. In cases complicated by

Fig. 868.—Tilden Brown's cystoscopic table with patient in position for examination.

cystitis, preliminary lavage of the bladder should be practised. This may be given through the cystoscope sheath or through a soft-rubber catheter. If the bladder is not diseased, it is merely necessary to draw off the urine. After the urine has been withdrawn, the cystoscope sheath should be firmly but gently held in place. The thumb of the left hand presses downward while the index-

finger presses upward on the under surface of the sheath. This procedure raises the beak of the instrument from the sensitive trigone, where most of the pain and hemorrhage are produced by vesical tenesmus.

In regard to the selection of the distending medium, the operator may use sterile water, normal salt solution, boric acid solution, or mercury oxycyanid solution (1:5000). The bladder should be moderately distended and, if possible, from 8 to 10 ounces of fluid are allowed to remain in the viscus. In contracted or hypersensitive bladders it is well to elevate the hips and so relieve the pressure on the sensitive vesical neck and trigone.

The temperature of the distending fluid is of great importance, particularly if there is difficulty in finding the ureteral outlet. If this is the case, the temperature of the fluid should be about 60° F. This enables the operator to see a so-called swhirl wnen the warm jet of urine mixes with the cold water in the bladder. It is sometimes advisable to give methylene-blue before examining for the same reason. The blue stream from the ureter at once identifies the tube.

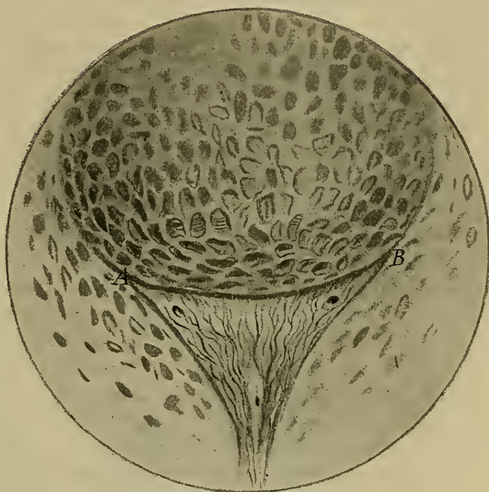

Fig. 869.—The interior of the bladder, showing arrangement of the vessels of the trigone: *A*, *B*, interureteral bar.

After the bladder has been filled the telescope containing the catheters is inserted and the light is turned on. The instrument, then held in the median line, is pushed gently back, well into the bladder, pressure being always made to keep the beak from impinging upon the floor of the viscus. The cystoscope is now slowly withdrawn, a careful watch being maintained through the telescope for the *interureteral bar* (Fig. 869). This structure (there has been much argument as to whether this structure really exists) marks the posterior border of the trigone. The examiner has still another guide to the trigone in the blood-vessels, which in a general way run anteroposteriorly. There is a distinct line of demarcation between the fish-net loop arrangement of the mucous membrane of the sides and base of the bladder and the mucous membrane in the trigone. Fig. 869 gives a general idea of the vascular arrangement. When the interureteral bar or posterior border of the trigone has been located, the instrument is gently and slowly moved laterally, so that the border of the cystoscope is kept in the field until the end of the bar is reached. The instrument is then held stationary for a moment and a sharp lookout is kept for the jet of urine or the swirl. The ureteral orifice is thus indicated. Should the field become blurred by blood on the lens, or should the solution in the bladder become mixed with blood, continuous irrigation must be kept up through the cystoscope.

The Ureteral Orifices.—As before mentioned, the ureteral orifices are usually located at the terminations of the interureteral bar, and occupy the basal angles of a triangle formed by the vesical outlet and the base of the trigone. They are usually about 1 to $1\frac{1}{2}$ cm. from the median line and about $2\frac{1}{2}$ cm. from the vesical end of the urethra. They are recognized as small slits or as tubercles on the surface of the mucous membrane. Their position is not always the same. Some of the abnormal positions more commonly met with are as follows: one

ureter closer to or further removed from the median line, both ureters emptying into the bladder close to the median line, generally about one-quarter or one-half the length of the bar. Malposition toward the vesical outlet and in some very rare instances both emptying on the same side. Sacculation and pocketing of the bladder with swelling of the mucous membrane often make localization of the ureteral orifices difficult. It is then that the administration of methylene-blue or indigo-carmin may enable the investigator to more readily locate the ureters.

After locating a ureteral orifice the vesical end of the cystoscope is carried directly over the opening and the catheter is projected against the opening, where it is allowed to remain for a moment in order to overcome the spasm of the sphincteric muscular fibers. The patient is instructed to hold his breath and the opening is carefully watched until a jet of urine is forced through, during which act the catheter is gently inserted into the ureter. The passing of the urine is accompanied by dilatation of the opening and greatly facilitates the passage of the instrument. After the catheter has passed the sphincter muscle it should be carried up the canal by *very gentle* pressure. The practice of passing the instrument quickly, so commonly resorted to by the novice in order to gain time, is pernicious, and almost invariably causes laceration and hemorrhage. Before inserting the catheter some operators prefer to coat it with paraffin in order to render it absolutely smooth and further to assist in the detection of calculus. This is not necessary. Any instrument with an imperfect eye should be discarded.

The round-pointed catheter should be used wherever possible, as with it there is less danger of injuring the delicate mucous lining of the canal. The sharp-pointed olivary tipped instrument often causes blood to appear. If possible, insert the catheter into the renal pelvis, for then hemorrhage from trauma is less likely to invalidate the examination, and spasm of the ureter, with sucking of the mucous membrane into the eye of the catheter, will not occur. Having finished the catheterization of one side, the catheter is left in place, the instrument handle is swung to the opposite side and a similar procedure is carried out. Always have a distinguishing mark upon the catheters. A very good method is to use different colored instruments, so that there may be no confusion after withdrawal of the cystoscope. In some cases only one ureter can be catheterized. In such a case the bladder should be thoroughly washed, and the other catheter, left on the floor of the bladder, will collect the urine from the uncatheterized side and give a fair idea of the condition of that kidney.

Removal of the Cystoscope.—The light should be turned off and a small amount of fluid allowed to escape through the barrel. The lens system carrying the catheter is then loosened and gently rotated from side to side to free the catheters. During this procedure the catheters are drawn gently backward, but not with sufficient force to cause kinking, and the lens system is removed. Next the sheath is withdrawn by carrying it straight up over the abdomen.

Collection of the Urine.—The protruding catheters are carefully wiped with sterile gauze and are permitted to drain into separate bottles or test-tubes, marked respectively right and left. The orifices of the receivers should be plugged with sterile absorbent cotton, which will collect and prevent any admixture of urine or water coming from the bladder by capillary drainage. The bottles should also be held in such position as to prevent such capillary drainage reaching them. With regard to the collection of the samples, there are certain precautions that should be observed: (1) The samples should, if possible, be collected in three separate bottles from each side, allowing each set to remain in position a definite time, generally one-half hour. These should be carefully watched and marked first, second, and third half-hours. They should each be

examined separately, and by a summation of the examinations the opinion should be reached. Almost invariably microscopical blood can be found in the urine drawn by catheterization of the ureters. In a study of 15 cases of normal ureters, blood not being present before catheterization after catheterizing with the greatest care, microscopical blood was present in all but 3. The erythrocytes are usually most numerous in the first bottle, gradually diminishing, until in the third there are very few or none. Should the blood increase in amount in the second or third bottle, it is an important clinical fact.

In some instances one or both catheters fail to drain. This may be due to a bubble of air in the instrument, impinging of the mucous membrane upon the eye, plugging by blood-clot, mucus, pus, or particles of gravel. A syringe is then essential. The blunt hollow needle should be inserted into the catheter and suction applied; should this fail, not over 4 c.c. of sterile normal salt solution may be injected through the catheter. This procedure, however, must be carried out very gently, because of the danger of overdilating the renal pelvis and thus producing colic.

The carrying capacity of the pelvis of the kidney is uncertain. Careful observations indicate that there is no definite carrying capacity that may be

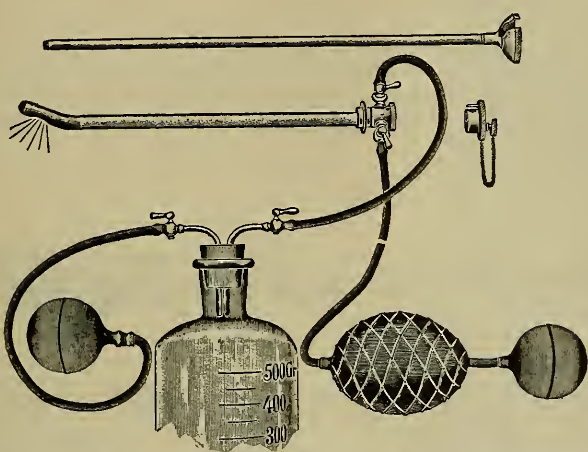

Fig. 870.—Bulbs and bottle for distending bladder and collecting washings.

called normal. The range of difference is great and even differs at certain times in the same kidney. In many kidneys it is about 8 to 10 c.c., but, on the other hand, it may be as high as 20 c.c. and still be normal. It would seem as though the blood-supply of the organ had something to do with the pelvic capacity, for a congested circulation means distended vessels, and they probably impinge upon the pelvis. Again, the question of producing renal colic by overdilatation of the pelvis is a very uncertain guide as to the capacity, for in many instances the ureteral and pelvic musculature is sufficient to force the fluid down the ureter with the catheter *in situ* and yet produce no evidence of colic. This has been seen in many instances in making a pyelographic study by means of a solution of collargol, which is much thicker than urine or water.

A uropyknometer is used for taking the specific gravity of small quantities of urine removed by the ureteral catheter.

The Operating Cystoscope.—The most practical operating cystoscopes are Bransford Lewis's and the A. C. M. I. instrument (see Fig. 865). These instruments greatly facilitate the removal of small portions of stone and foreign bodies from the bladder and the ureteral orifices. They are also useful for making ap-

plications to ulcerated areas. It is not wise to remove papillomatous tumors by them, as most villous papillomatous growths sooner or later exhibit the elements of malignancy and should have their pedicles removed with a portion of the vesical wall, which can only be safely done after suprapubic cystotomy. We have succeeded in fulguration of intravesical papillomata of a benign type

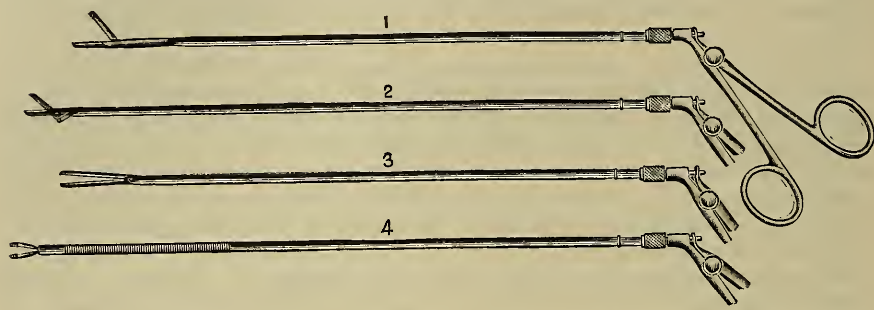

Fig. 871.—1, Scissors; 2, tweezers; 3, forceps; and 4, punch for use with the Lewis's cystoscope.

by means of the high-frequency current, and Prof. Hiram R. Loux has had several such cases that have remained well for over two years.

Practical Value of Cystoscopy and Ureteral Catheterization.—The cystoscope has attained a very important position in the surgeon's armamentarium. It undoubtedly affords the best method of establishing an accurate diagnosis

Fig. 872.—"Universal" cystoscope with wire snare.

founded on pathological findings. By it one is enabled to determine the presence and character of cystitis, stone, foreign bodies, and malformations. Without it the presence of ulcerations could merely be guessed at by the clinical history. Its greatest field is in the early diagnosis of the cause of renal and vesical hemorrhages. In the detection of renal neoplasms it may be said to have revolutionized surgery. It makes possible the early removal of such

Fig. 873.—Lewis's repositor.

growths before malignancy has signed the patient's death warrant. Cases of prostatic hypertrophy, in which the lobes project backward, cannot be accurately diagnosticated without the cystoscope; with it the parts can be seen and the clinical diagnosis positively confirmed. It makes possible the removal of small foreign bodies, such as stone, pieces of cotton, or filiform bougie through the urethra, thus saving formidable cutting operations. It is needless to mention the great difficulty found by surgeons in former years in determining the source

of symptomless hemorrhage, a problem which is now comparatively easy of solution.

Ureteral catheterization makes possible the irrigation of the ureter and pelvis of the kidney in cases of ureteritis and pyelitis.

The technic of lavage is as follows: The gravity tubes for instilling fluid, shown in Fig. 874, are carefully sterilized and the metal nozzles arranged so as to fit correctly the lumen of the ureteral catheters. It is always necessary to make certain that the nozzles will fit and that they and the catheters are free. This should never be neglected. It has been found on several occasions that one or the other was blocked, and, again, any particles of catheter or other material that might form a nidus for stone formation should be washed out. We advise the irrigation to be done by means of gravity in preference to a syringe, as the fluid may be delivered more evenly and, so to speak, may be "sneaked" into the pelvis of the kidney. This gentle trickle of warmed fluid does not seem to excite acutely the musculature of the ureter and pelvis; in consequence there is not so much colic, and when colic occurs it does not persist so long. About this point there has been some difference of opinion, but the evidence is in favor of the gravity method both for lavage and pyelography.

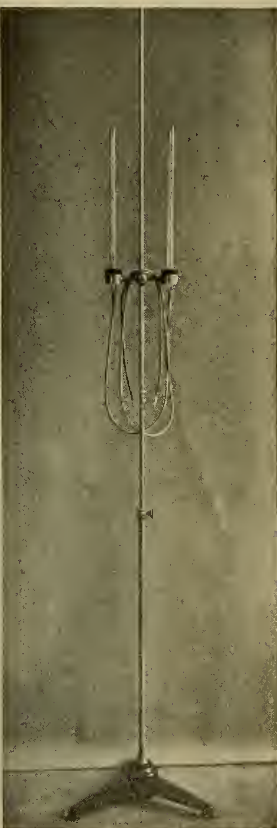

Fig. 874.—Apparatus for filling pelves in pyelography; also for doing lavage of ureters and pelves.

There are several solutions that may be used. We believe that normal salt solution is the best for mere cleansing purposes. Saturated solution of boric acid may be used if a mild antiseptic is needed. Either of these solutions may be followed by the different silver solutions in strengths calculated to suit the case in hand. The nitrate of silver is generally used in a strength of 1:8000, but a much stronger solution may be resorted to. In the clinic of Prof. Loux excellent results have been obtained from a 10 per cent. solution of argyrol.

The catheters are passed into one or both ureters and the fluid is permitted to pass very slowly into the pelvis or ureter, as the case may be. Overdistention must be guarded against, and a safe rule is not to allow over 8 c.c. to be used at any one time.

The type of catheter to be used may be according to the fancy of the operator. There is at present a very excellent two-way pelvic irrigating ureteral catheter, or the single tube instrument may be used and the fluid allowed to escape after filling the pelvis. This procedure should be repeated until the return fluid is clear. Should hemorrhage complicate the procedure, an irrigation of adrenalin may be used. (This has been known to apparently cure essential renal hematuria.)

After completion of the irrigation the bladder should be thoroughly washed and the patient put upon some mild genito-urinary antiseptic, of which there are several to choose from. Urotropin is the one usually given.

It would seem a wise plan to thoroughly irrigate the kidney, pelvis, and ureter before certain surgical operations. When a surgeon is going to open the kidney in the presence of pus or infected urine, before cutting down upon the kidney it is well to wash away as much as possible of the purulent matter

through a ureteral catheter and then instil some nitrate of silver or collargol, which is the silver preparation used in making pyelographic studies.

Irrigation of the pelvis and ureter has come to be a rational surgical procedure and in many cases is followed by a marked improvement in the general health of the individual, making operative procedure safer and not complicated by so marked a toxemia. In all cases when operative work is to be done on a kidney with a large pus sac of other than tuberculous origin, irrigation of the pelvis by means of one of the milder antiseptic silver solutions would seem to be a proper surgical procedure. It is especially so when the necessity may arise for opening the peritoneal cavity.

A differential diagnosis must sometimes be made between gall-bladder disease, appendicitis, and movable kidney with dilated pelvis. This is done by determining the carrying capacity of the pelvis by means of the injection of

Fig. 875.—*A*, Dilated kidney pelvis filled with collargol solution; *B*, kink in ureter; *C*, dilated ureter filled with collargol solution; *D*, constriction of ureter; *E*, ureteral catheter. (Taken by Dr. W. F. Manges.)

salt solution and by making a pyelograph (Fig. 875). If the trouble is with the kidney, pain caused by injection of salt solution will be similar in character and situation to the pain of the attacks. As a rule, in movable kidney producing marked symptoms the renal pelvis is dilated. When the trouble is due to the kidney the pain induced by the distention is similar to that from which the patient has suffered (Howard A. Kelly). If a stone is present in the ureter the x-ray picture will usually reveal it, but here again there may arise doubt as to the exact course of the canal. Catheters passed into the ureters, each catheter with a lead wire in it, can be skiagraphed, and the radiographer will be able to determine the exact course of the ureters. Instead of a catheter containing a wire the x-ray catheter of Eynard may be used. Figure 876 demonstrates the practical utility of such manipulation. Phleboliths, fecal masses, appendoliths, concretions, and calcified lymph-nodes have been mistaken for ureteral stone

even after a study of skiagraphs. Appendices have been removed when the source of trouble has been impacted stone in the right ureter. In 3 cases seen by Stellwagen appendectomy had failed to cure. In each case a stone was subsequently removed from the ureter and the patient cured. An impacted stone in the ureter may often be dislodged by passing a catheter into the ureter and, if possible, beyond the stone. A few minims of sterile olive oil are then injected through the catheter, which act as a lubricant and assist in the passage of the stone. Dilatation of the ureteral orifice, by leaving the catheter *in situ* or passing a second instrument alongside of the first, will often cause the stone to pass into the bladder.

Disinfection of Urethral Catheters.—Metallic instruments are cleansed by boiling. Soft-rubber and elastic catheters can be sterilized by mechanical cleansing with soap and water and boiling for five minutes. The common custom of immersing a soft-rubber or elastic catheter for five minutes in a 1 : 2000 solution of corrosive sublimate is a useless waste of time, as such a

Fig. 876.—*X*-ray photograph, showing the course of the ureters by wires in the catheters. (Taken by Dr. W. F. Manges.)

procedure will not sterilize an infected instrument. Formalin vapor is not reliable. A catheter coated with varnish or resin cannot be placed in steam, and cannot be boiled in water if it is allowed to touch the metal of the boiler or another catheter. Woven and varnished instruments can be boiled in salt water (3 drams of salt to 1 pint of water), provided each instrument is wrapped in a piece of gauze so that it cannot touch another instrument or the side or bottom of the metal sterilizer. This plan secures the most certain sterilization. Catheters, after being cleansed mechanically and disinfected, may be kept ready for use in a glass cylinder containing calcium chlorid (R. W. Frank, in "Berliner klin. Woch.," No. 44, 1895). By this plan the catheters can be kept straight. Some prefer to keep them in a glass cylinder containing a few formalin tablets.

An excellent way to keep sterile catheters clean is to place each catheter in an individual bag of linen or waxed paper. Stellwagen boils a number of rubber condoms at the time he boils the catheters. When the instruments

and condoms are dry he encloses an instrument in each condom. Before using catheters which have been in formalin vapor they must be washed in sterile water or salt solution.

Diseases and Injuries of the Bladder

Retention of Urine in the Male.—Retention of urine is not, of course, a disease; it is rather a result of one of a number of different diseases. By this term is meant an absolute inability to micturate voluntarily. The retention may be *complete*, not a drop emerging, or it may have been complete, a dribbling setting in after a time, due to paralysis of the bladder, which viscus becomes unable to contain more fluid, expulsion of the overflow from the ureters being produced by atmospherical pressure. This condition is known as *the engorgement, the overflow*, or *the incontinence of retention.* There may be *retained* urine in a man with enlarged prostate, a portion only of the urine being voided. This is not retention, and the urine so retained is called *residual urine.* Of course, true retention may arise in a person with enlarged prostate. Retention may be caused by: (1) *Obstruction*, resulting from urethral stricture, hypertrophied prostate, inflamed prostate, occluded meatus, impacted calculus or foreign body, urethral tumor, rupture of the urethra, perineal abscess, imperforate prepuce, congenital phimosis, tumor of the penis, tumor of the prostate, prostatic abscess, abscess of the penis, ischiorectal abscess, and pressure from a large pelvic tumor. The commonest obstructive cause is spasm of the membranous urethra arising during the existence of stricture, acute gonorrhea, or gleet. (2) *Defective expulsion*, resulting from impairment of the nervous apparatus for inducing micturition. Hysteria is a rare cause in men. We see retention without obstruction after vertebral fractures or spinal concussion, in certain diseases of the spinal cord, sometimes in shock and peritonitis, often in the continued fevers and diseases characterized by muscular wasting, from the action of certain drugs (belladonna, opium, or cantharides), and after certain surgical operations upon or about the rectum. The last-named form of retention is due either to reflex inhibition of the expulsor muscle or to reflex stimulation of the sphincter vesicæ, causing it to remain firmly contracted. *Acute retention* comes on suddenly and is sometimes the first thing that causes a sufferer from urethral stricture to seek a surgeon.

Symptoms.—In *acute retention* there is an agony of desire to urinate, the patient making acutely painful straining efforts, during which feces are often passed. There are severe pain and aching in the abdomen, thighs, perineum, and penis. All the symptoms rapidly increase, a typhoid state is inaugurated eventually, and death closes the scene unless relief be given. If retention is from time to time alleviated by the passage of a little water, the symptoms are slower in evolution and are less intense, and the case is said to be *chronic.* Some cases of gradual onset due to atony are very insidious, the patient feeling no particular pain and complaining only of the dribbling, which is really the overflow of retention, and is not a sign that the bladder is successfully emptying itself. In any case of retention the bladder rises above the pubes, and there is found a pyriform, elastic, fluctuating mass in the hypogastrium, which mass is dull on percussion and gradually enlarges until the bladder is evacuated or incontinence sets in. The flanks give a clear percussion-note, and the tumor is more prominent when the patient is erect than when he is recumbent. Long continuation of obstructive disease, producing partial retention with or without attacks of complete retention, disorganizes the kidneys. Acute and complete retention may induce rupture of the urethra or urinary suppression.

Treatment of Retention of Urine.—Place the patient upon his back and, if possible, upon a hard mattress. If the bed is so soft that the hips sink down in it, put an ironing board or some other support beneath the mattress at the level of the buttocks. This will greatly facilitate catheterization. Never attempt to use a catheter when the patient is erect; to do so may cause serious or even fatal shock. Always keep the patient protected from cold. Obtain a full history of the case and always make a gentle rectal examination of the prostate; also examine the external genitalia. Failure is often traceable to a lack of thorough examination. It is evident that retention due to prostatic disturbance is not to be dealt with in the same manner as retention due to stricture, impacted stone, etc. If instrumentation does not rapidly succeed, give an anesthetic. Be sure that every instrument is aseptic, and irrigate the urethra before and after instrumentation. Grease the instruments with liquid cosmolin. Prolonged attempts to introduce a catheter and excessive instrumentation are highly dangerous, especially in prostatic cases. Dreadful damage may be inflicted. There is no operation in surgery that requires a gentler touch. Haste, eagerness, carelessness, roughness are, alike, taboo. If a non-medical person knew the facts he would give more thought in the selection of a surgeon to relieve him of retention of urine than of a surgeon to amputate his leg. A surgeon with retention would give grave thought to the question. When the instrument enters the bladder, draw off but half of the urine, withdraw the instrument, wait a few hours, insert it again, and then empty the bladder and wash out the viscus with warm boric acid solution. To draw off all of the urine at once is dangerous, because the sudden relief of the pressure upon distended veins leads to bleeding from the mucous membrane and hemorrhage into the bladder walls. After the bladder has been emptied the patient is wrapped in blankets, a bag of hot water is placed against the perineum, and a hot-water bag is laid upon the hypogastric region. If no anesthetic was used, he is given, at once after the operation, a suppository of opium and belladonna. If an anesthetic was used, he is given the suppository when he recovers from the effect of the anesthetic. Tablets of salol and boric acid are administered during the several days which immediately follow the operation. If the cause of retention is organic stricture, try to pass an elastic, olivary pointed catheter (Fig. 877, *a*). Do not use any force until the neck of the elastic catheter is well engaged in the stricture. Then an experienced operator may warily use a certain amount of force, but never an amount which much exceeds the slightest. If it is found impossible to pass an elastic instrument, make an attempt to carry a filiform whalebone bougie into the bladder. Fig. 878 shows filiform bougies. If the history shows that the man has long had an organic stricture, do not waste time with the gum catheter, but at once proceed to use the filiform bougie. On this bougie, after it has been inserted, Gouley's tunnelled catheter can perhaps be threaded (Fig. 879) and carried into the bladder. Instead of carrying in the catheter, we can simply leave the filiform bougie in place and fasten it. The filiform bougie will act as a capillary drain, and in a few hours will empty the bladder and will also dilate the stricture. Then insert another bougie beside the first, and so on for several days, using also opium, order-

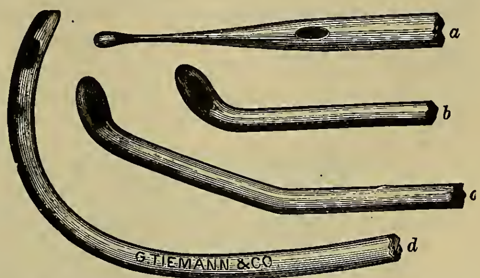

Fig. 877.—*a*, French olivary gum catheter; *b*, Mercier's elbowed catheter (coudé); *c*, Mercier's double-elbowed catheter (bicoudé); *d*, curved gum catheter.

ing rest in bed, and making no attempt to dilate the stricture forcibly until retention has ceased and inflammation has subsided. Perhaps Phillips's catheter (Fig. 883) can be passed. If no instrument can be passed, aspirate above the pubes or perform cystotomy (suprapubic or perineal). In *spasmodic stricture* hold a good-sized metal catheter firmly against the face of the spasmed area; relaxation will occur and the instrument will eventually

Fig. 878.—Points of Gouley's whalebone guides (filiform bougies).

Fig. 879.—Gouley's tunnelled catheter threaded on a filiform bougie.

pass. Fig. 880 shows the proper curve of a metal instrument. An individual who has an organic stricture which has given but little trouble may develop attacks of retention because of inflammatory edema of the mucous membrane and spasm of the urethral muscles. These attacks are temporary, and an instrument can usually be inserted when employed as above directed. In *inflammation* give a hot hip-bath and suppositories of opium and belladonna, and then use a hot sand-bag to the perineum and a hot-water bag

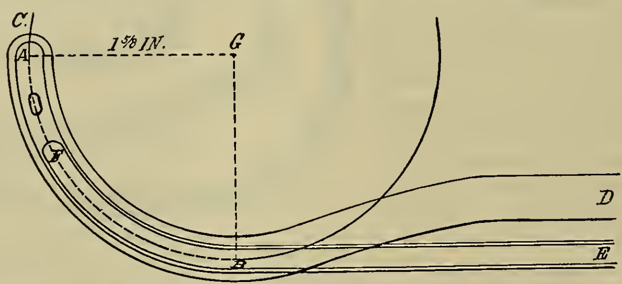

Fig. 880.—*A–B–E* shows the proper curve (reduced in size) for unyielding male urethral instruments; *C–B–D* shows an improper curve.

over the hypogastrium. If these fail or if the symptoms are urgent, pass a soft catheter. In the *occluded meatus of the newborn* incise with a tenotome. In a *congenital cyst of the sinus pocularis* pass a steel bougie, which will rupture the cyst. In *complete phimosis* split up the prepuce. In *impacted stone* try to pull out the calculus with urethral forceps; if this fails, cut the urethra or, in rare cases, push the stone back into the bladder. In *fecal impaction* scrape

Fig. 881.—English silk-web catheter.

out the rectum with a spoon. In *enlarged prostate* the rectal examination gives information as to the type of enlargement. If there is moderate enlargement of the middle lobe the coudé (Fig. 877, *b*) or the bicoudé catheter (Fig. 877, *c*) will probably pass. If these instruments fail, try the overcurved silver catheter of Sir Benjamin Brodie. This metal instrument has a large curve and will probably succeed, but it is a dangerous tool and one capable of inflicting grave injury. In enlargement of one lateral lobe with possible deflection of the

urethra and valve formation try, in order, the woven silk catheter (Fig. 881), the Nélaton catheter (Fig. 882), strengthened by having a filiform passed in its lumen nearly to the beak, and the rat-tailed silk instrument. In enlargement of both lobes and the middle lobe try the coudé, then the bicoudé, then a coudé and a bicoudé with olivary or rat-tailed tips. If all of these fail, the overcurved metal catheter of Brodie must be used gently. In *retention from expulsive defect* use a soft catheter (Fig. 882). Cases of retention after catheterization require warmth, confinement to bed, the administration of laxatives, free action of the skin, and the use of such drugs as salol, boric acid, urotropin,

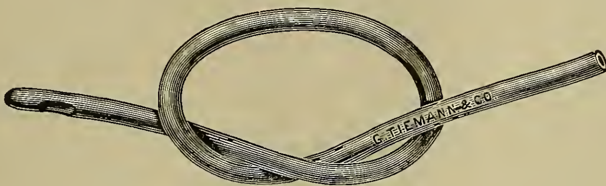

Fig. 882.—Nélaton's catheter.

and quinin to asepticize the urine. In some few cases no instrument can be inserted in the bladder. In most of such cases aspirate—which may be done several times if necessary—and in a day or two, when swelling and congestion abate, an instrument can be passed. The parts are asepticized. A small aseptic trocar or aspirator needle is pushed into the bladder, the trocar or needle being inserted in the median line, just above the pubes, and taking a course downward and backward. After the completion of the operation the puncture is dressed with iodoform and collodion. Only half the urine is with-

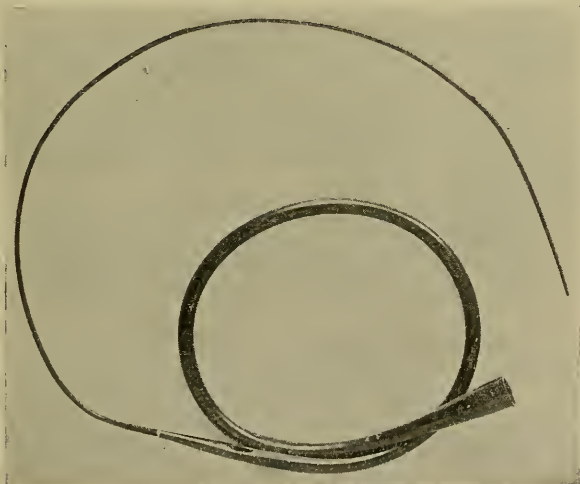

Fig. 883.—Phillips's catheter.

drawn at a first aspiration. Rectal puncture is now obsolete. If incision is necessary in retention, the perineal route is usually chosen. In some cases the operation is done with, in some without, a guide. In prostatic retention not relievable by a catheter, make suprapubic drainage or do prostatectomy.

Congenital Defects of the Bladder.—**Exstrophy of the bladder** (*ectopia vesicæ*) is a condition of defective development commoner in males than in females. The anterior abdominal wall has failed to close, the anterior wall of the bladder is absent, the arch of the pubes has not developed,

epispadias exists, and in many cases the testicles have not descended into the scrotum. In this condition the posterior wall of the bladder projects into or beyond the gap in the abdominal wall; the urine constantly flows and renders the condition of the patient dreadful. The condition shortens life and only 30 per cent. of the victims live beyond the twentieth year, death being due to pyelonephritis.

The only treatment which offers hope is operation, and operation often fails. If possible, operate when the patient is about five years of age. Various operations have been suggested for this condition, viz.: covering with skin-flaps; implanting the ureters into the bowel (Maydl, Albert, Roux, Simon, and others); division of the posterior ligaments of the sacro-iliac joints, bringing the arch of the pubes forcibly together, the patient wearing a support until the parts become firm, when the greatly narrowed defect is closed in by integumentary flaps and suturing the bladder edges (*Trendelenburg's operation* or *synchondroseotomy*); osteotomy through one ilium or both ilia instead of separation of the sacro-iliac joints (*Berg's operation*), or after extirpating the bladder, loosening the ureters from the bladder, drawing them down and attaching them to the end of the penis (*Sonnenberg's operation*).

A bladder closed in by autoplasty, by Trendelenburg's operation, or by Berg's operation is never really continent, although when the patient is erect and wears a light compress he may perhaps be able to hold water two or three hours. The above methods are suited to young children and are far safer than ureteral transplantation. Tuffier showed, nearly twenty years ago, that transplantation of the cut ureters into the bowel was certain to be followed by fatal infection of the kidney, and that the only way to prevent this was to retain the ureteral orifices which contain valves.

Maydl introduced his operation in 1892. He implanted the trigone with the ureters into the sigmoid flexure, extirpating the rest of the bladder. I have twice performed a modified Maydl's operation, with one death and one recovery. Buchanan ("Surg., Gynecol., and Obstet.," Feb., 1909) has collected 80 cases. In this collection there were 23 deaths (28.7 per cent.); 7 died of peritonitis and 9 of pyelonephritis. Bregenhem in 1894 devised extra-peritoneal implantation of the ureters and a portion of bladder through two separate openings into the rectum.

Diseases and Injuries of the Bladder.—This viscus is so deeply situated, and the abdominal walls are so elastic, that it is rarely injured when empty. If the bladder is full and the abdomen tense—which is common in alcoholic intoxication—force applied upon the abdomen may injure the bladder.

Contusion of the Bladder.—In this condition there are noted vesical hematuria, tenesmus, severe cystitis, and an impediment to the flow of water because of clots. Hemorrhage may be very severe and sepsis may arise, even causing death. When contusion exists retention is relieved by means of a clean soft catheter; if this fails because of occlusion of the eye of the catheter with blood-clot, at intervals there must be passed through the catheter from a fountain-syringe a solution of sodium bicarbonate in cooled boiled water. Gross's blood-catheter can be used or the evacuator of Bigelow may be employed. The patient is put to bed, a hot-water bag is applied to the hypogastrium, morphin is administered in moderate doses, the bladder is washed out several times a day with boric acid solution or a solution of bicarbonate of sodium to disintegrate and remove blood-clots, and the urine is diluted and rendered aseptic by the stomach administration of salol, boric acid, and the free use of bland fluids. Hemorrhage usually ceases on relieving distention; if it does not, some more radical measure must be employed (see Hematuria).

Wounds of the Bladder.—Besides being contused, the bladder may be injured by bullets; by stabs or punctures through the abdomen, the vagina, or the uterus; or by penetration by a fragment of a fractured pelvic bone. The symptoms of such conditions are those of rupture of the bladder (*q. v.*). In an intraperitoneal wound at once open the abdomen, suture the wound in the bladder wall, irrigate and drain the peritoneal cavity, and drain the bladder by means of a retained catheter, perineal section, or suprapubic cystotomy. In an extraperitoneal wound drain the wound by a tube, and drain the bladder by a retained catheter, perineal section, or suprapubic opening.

Rupture of the bladder occurs in three forms: (1) intraperitoneal—a rupture involving the peritoneal coat; (2) extraperitoneal—a rupture of a portion of the bladder not covered by peritoneum; and (3) subperitoneal—a rupture of the mucous and muscular coats, the urine diffusing under the peritoneal investment. The *causes* are of two kinds, predisposing and exciting. *Predisposing* causes are: distention of the bladder; drunkenness; cystitis; ulceration; degeneration or atony of the bladder-coats; prostatic enlargement, and urethral stricture. Distention of the bladder is the great predisposing cause. It causes the bladder to rise from the pelvis and so become exposed to a direct blow, it places the organ under tension, and force tends to rupture the weakest point. In about one-third of the cases collected by Bartels the individual was intoxicated at the time of the accident. Drunkenness predisposes because a drunken man is very liable to injury and is apt to have a distended bladder and a rigid belly wall. Males are much more liable to rupture than females (10 to 1). Most cases are between the ages of twenty and forty. Of Besley's 25 cases, 1 was a child of three, 1 a man of forty-nine, 3 were in the first and second decades, 5 were between twenty and thirty, 7 between thirty and forty, 6 between forty and fifty, and in 2 the age is not given (paper before Chicago Surg. Soc., Feb., 1907). The condition is very rare in children, but 1 of Besley's cases was three years of age, and King recorded the accident in a fetus with imperforate urethra.

Exciting causes are: obstruction to the outflow of urine (by stricture or enlarged prostate); external violence; falls upon the feet or the buttocks, as well as upon the abdomen; lifting; straining at stool, in micturition, or during parturition; and the forcing of injections into the bladder. A distended bladder may be ruptured by a concussion. The most usual cause of the injury is a crush. The mechanism of the injury is in dispute. It is certain that the bladder must have lost its elasticity by distention. When force is applied to fluid (fluid is incompressible) the bladder tears at its weakest point. The weakest point is not identical in all individuals. It may be weak anywhere from disease. The most common site of the tear is at the posterosuperior aspect, but it may be in front, at either side, or at the pubic or prostatic ligament (Staubenranch). The mucous membrane or the peritoneum may give way first and the tear may be anteroposterior, oblique, or longitudinal. Alexander maintains that the most usual cause of the injury is a crush which forces the distended bladder against the sacral promontory, but Besley's (Ibid.) experiments do not indicate that this is correct. A common complication, especially of extraperitoneal rupture, is fracture of the pelvis, due to the same force that ruptured the bladder.

Symptoms, Diagnosis, and Treatment.—The symptoms are not always definite, and every characteristic one may be for a time absent, the patient seeming in some rare instances of extraperitoneal and intraperitoneal rupture to possess the power of retaining his urine and of voiding it. As a rule, however, there are found some or all of the following symptoms, following an accident or occurring during the progress of a causative disease: severe pain in the bladder and in the suprapubic region, collapse; inability to walk or great difficulty

in walking; excessive desire to micturate, but inability to do so (sometimes a little pure blood or bloody water is squeezed out by painful effort); a catheter, when used, brings away pure blood or a very little bloody urine; the catheter occasionally slips through the tear into the cavity, and more bloody water comes away. In some reported cases clear water has been withdrawn. If a measured amount of boric acid solution is injected, it is improbable that all of it can be withdrawn by the catheter, although in some cases it may all come away (Alexander, in "Annals of Surgery," August, 1901). Injecting fluid fails to lift the bladder into the hypogastric region so as to be recognizable on percussion. In a patient suffering from retention of urine in whom rupture occurs there is first a temporary sense of relief from retention, but very soon severe hypogastric pain and rectal tenesmus. In intraperitoneal rupture reaction may be obtained after a few hours or a number of hours. The evidences of peritonitis will be noted soon (rapid pulse, perhaps vomiting, rigidity, distention, obstruction of the bowel, elevated temperature, etc.). Shock in vesical rupture is so severe that death may ensue; if reaction follows, there may be delirium and often septicemia; extensive infiltrations of urine may occur. In *intraperitoneal rupture* general peritonitis is certain to arise, but its appearance may be postponed for several days if the urine is healthy. In these cases the extravasation is noted as a simple swelling, probably on one side only. In *extraperitoneal rupture* the urine may infiltrate the perineum, the scrotum, the thighs, and under the integuments of the abdomen and the back, and may soon induce sloughing. In *subperitoneal rupture* peritonitis is apt to arise.

In doubtful cases some surgeons pump air or hydrogen into the bladder. To insert air a bicycle pump can be used (Brown) or a Davidson syringe (Keen). Keen's directions are to insert a catheter, empty the bladder of urine, and connect to the catheter a disinfected Davidson's syringe, a mass of absorbent cotton being fastened over the distal end of the syringe. Air after it has filtered through the cotton is pumped into the bladder; an unruptured bladder will rise above the pubes as a pyriform tumor, tympanitic on percussion. A ruptured bladder will not so rise. In intraperitoneal rupture the air will pass into the general peritoneal cavity and distention will occur. In extraperitoneal rupture injection will produce emphysema of the extravesical connective tissue. On removing the syringe the air rushes out again if the bladder is unruptured, but little if any comes away if it is ruptured. Alexander considers gaseous distention unreliable, and claims that it adds to shock and disseminates infection. His rule is the wisest to follow; that is, in a case of suspected rupture of the bladder, make a suprapubic incision and inspect the prevesical space for signs of extraperitoneal rupture. If extraperitoneal rupture is not found, open the belly and explore.

Treatment.—In extraperitoneal rupture, after incision down to the bladder insert a drainage-tube. In intraperitoneal rupture, place the patient in the Trendelenburg positon, expose the tear in the bladder by abdominal incision, and suture the opening in the viscus.

Results.—Baron Larrey was the first surgeon to state that a wound through all the coats of the bladder might be followed by recovery. In intraperitoneal ruptures if operation is not performed the mortality is 98 per cent. If operation is performed many cases recover. Of the 78 cases collected by Dambriu and Papin in 1904, 34 died, a mortality of 43 per cent. (Besley, paper before Chicago Surg. Soc., Feb., 1907). Galactionoff ("Rovssky Vratch," Nov. 12, 1910) reports 15 cases operated upon for intraperitoneal rupture; 5 recovered (3 of them were operated upon during the first twenty-four hours; 1, after thirty-six hours, and 1, after forty-eight hours). In extraperitoneal rupture without operation there are 11 per cent. cures and with operation 30 per cent.

(See Daniel N. Eisendrath, "Jour. Amer. Med. Assoc.," Oct. 25, 1902; Samuel Alexander, "Annals of Surgery," Aug., 1901.)

Atony of the bladder is a condition in which the expulsive power of the bladder is diminished or lost because of impairment of muscular tone. The bladder is very thin, and the muscles are flaccid and often the seat of fatty degeneration. Sometimes the viscus is very large and sometimes it is very small. A slight degree of atony is physiological after middle age.

The **causes** are senility, distention from true paralysis, chronic overdistention from obstruction, and acute overdistention. In most cases there is obstruction of the urethra. In that rare condition known as *idiopathic atony* there is no evidence of obstruction. Walker ("Annals of Surgery," Nov., 1910) reports 12 cases of idiopathic atony. He says the patients were between the ages of twenty-two and forty. He regards the condition as due to a lesion in the reflex centers.

Symptoms.—In atony of the bladder the patient passes water frequently (a symptom probably existing for some years), and especially at night; he may even do so while asleep. The stream, when voluntarily passed, has little projection, but seems to drop at once from the end of the penis. Residual urine exists for years and may at any time set up cystitis, and retention with incontinence is apt to occur. This condition is *not* vesical paralysis resulting from a lesion of the nervous system.

Treatment.—In treating atony of the bladder measure the residual urine: if it amounts to 4 oz., use a soft catheter night and morning; if it amounts to 6 oz., use the catheter every eight hours; if it amounts to 8 oz., use the catheter every six hours (J W. White). The patient should be taught how to use the catheter and how to keep it sterile. (For Methods of Disinfecting Catheters see article on page 1311.) The bladder is from time to time washed out with 3 gr. to the ounce of boric acid solution at a temperature of 100° F. Strychnin, electricity, ergot, and urotropin may be ordered.

True Paralysis of the Bladder.—Vesical paralysis results from a lesion of the nervous system causing paralysis of the motor nerves or of the motor paths from which they are prolongations (fracture of the vertebræ, spinal meningitis, syphilis of the cord, myelitis, and hemorrhage about or into the spinal cord). A traumatic paralysis comes on suddenly. Hysteria may be responsible for temporary palsy. If the detrusor muscles alone are palsied there is complete retention of urine. If the sphincter is paralyzed the urine dribbles constantly. Even when there is dribbling a quantity of urine is retained below the level of the internal meatus. In such a case there is incontinence with partial retention (the *overflow* of Sir Henry Thompson). If the patient sits down or assumes the knee-chest position he may empty the bladder by contracting the abdominal muscles. In cases of real retention the detrusors may be temporarily paralyzed. In such a case the sphincter may finally relax from fluid pressure, and atmospherical pressure or contraction of abdominal muscles may cause urine to dribble, the bladder remaining full (the *overflow of retention* of the elder Gross). In some cases of vesical paralysis there is retention; in some cases, incontinence of urine. If the sensory as well as the motor path is involved in a lesion, the patient has no sensation to notify him of dribbling or of retention.

Treatment.—Treat the cause. Employ regular aseptic catheterization by a soft instrument. In some cases the bladder may be subjected to faradism (one electrode in the bladder and one in the perineum or on the abdomen above the pubes). Kilvington ("Brit. Med. Jour.," 1907, vol. i) pointed out that the nerve-supply of the bladder and rectum is from the second and third and sometimes also from the first sacral nerves. He suggested treating some otherwise incurable cases of vesical paralysis by anastomosing a nerve-root above

the lesion to certain sacral nerves below the lesion. Bird did the first operation, but it failed. Mills and Frazier (see page 863) performed intradural anastomosis of the last lumbar nerve to the third and fourth sacral nerves. The patient was much benefited ("Jour. Amer. Med. Assoc.," Dec. 21, 1912).

Foreign Bodies in the Bladder.—The term "foreign body" is, at best, a poor one, since a stone is a foreign body. The term, however, is generally used to designate material held within the viscus and of purely extraneous origin. There have been a great variety of foreign bodies removed from both the male and female urinary bladder. We have seen a lead-pencil, hair-pins, a willow twig, a glass rod, and a piece of chewing gum removed, as well as portions of catheters and filiform bougies. For reports of foreign bodies found in the bladder the reader is referred to text-books upon genito-urinary diseases.

Most of the foreign bodies are found in the bladders of masturbators. In them the glans penis or the clitoris have become so inured to friction that they must seek deeper for sensation, and consequently men resort to titillation of the verumontanum and posturethra, and women, to irritation of the vesical neck. The object used to stir sensation may slip from the grasp and pass backward into the bladder. The careless use of the filiform bougie is a great danger. Always test the filiform for defects and for tensile strength before using it. Should you be using the Gouley catheter, see that the tip through which the filiform must lace is not sharp or square, else it may shear off a portion of the bougie. All foreign bodies sooner or later induce cystitis. Every foreign body if allowed to remain will become encrusted with urinary salts and form a nucleus for stone formation.

Diagnosis, Symptoms, and Treatment.—*Diagnosis* is made by the history, if given correctly, of the case. The stone-searcher, the x-ray, and the cystoscope are most useful in diagnosis. The *symptoms* are similar to those of stone in the bladder. The *treatment* is removal, with subsequent care of the resultant cystitis.

Vesical Calculus, or Stone in the Bladder.—The salts normally in solution in the urine may deposit as calculi and may be imprisoned in any portion of the urinary tract. The commonest primary calculi are those composed of uric acid, urates, calcium oxalate, and fusible phosphates. In 80 per cent. of cases primary calculi are composed of uric acid and urates. A primary calculus may become coated with another material (secondary calculus). The formation of uric acid and urate calculi is explained under Renal Calculus (see page 1283). Vesical calculi are usually renal calculi that have passed the ureter and become enlarged by new accretions. New accretions from an alkaline urine will cause the formation of a secondary phosphatic stone. Phosphatic calculi may be formed in the bladder when chronic cystitis causes and maintains an alkaline urine. Uric-acid calculi are smooth, round or oval, and hard, but easily broken. On section they present the color of brick-dust and are marked by concentric rings. Their nuclei are dark by comparison. They are soluble in dilute potassium hydrate and in nitric acid. They are combustible and leave scarcely any ash. Urate of sodium and urate of ammonium often occur together in stones, and these calculi are not in rings, are not so hard as the uric-acid stones, and are fawn colored on section. Oxalate of lime stones are round, with many projecting nodes like the mulberry, hence the term "mulberry calculus." They are very hard, and section shows the color to be brown or green and that they possess wavy, concentric rings. This form of calculus is soluble in hydrochloric acid. The so-called fusible calculus of the early writers, which is composed of a phosphate of magnesium, ammonium, and calcium (*triple phosphate*), constitutes the commonest form of phosphatic stone and of large stone. It is light, soft, smooth and white, and shows no laminæ on section. Some rare forms of primary stone are composed of xan-

thin, cystin, indigo, urostealith, calcium phosphate or calcium carbonate, or blood concretions.

A stone having layers of different substances may be formed; for instance, there is often found a uric-acid nucleus surrounded by phosphates, the latter surrounded by some uric acid or urates, and these again by phosphates. In some cases oxalate of lime alternates with uric acid, urates, or phosphates (Bowlby). Bowlby states that the alternating uric-acid and phosphatic layers are due to the altering reactions of the urine; that when the urine is acid uric acid is deposited on the stone, but when cystitis makes the urine alkaline the stone receives a phosphatic coat.

Anything that favors the formation of an excessive urinary deposit may cause vesical calculus, and among such causes are defective digestion, failure in processes of oxidation, excess of solids and nitrogenous elements in the diet, deficient exercise, etc. If to the urinary condition established by the above factors catarrh of the genito-urinary tract is added, pus or mucopus in the

Fig. 884.—Stone in bladder shown by *x*-rays.

concentrated urine may induce stone. Children are predisposed to uric-acid stones, and old people to phosphatic stones. In an old man with enlarged prostate and chronic cystitis a stone forms rapidly about any accidental nucleus. The nucleus may be phosphate crystals glued together by mucus, a blood-clot, uric-acid gravel, or a foreign body. Stone is rare in females because of the shortness, the large diameter, and the ready dilatability of the urethra. Stone is very rare in the negro. Gout, rheumatism, lithemia, enlarged prostate, vesical atony, urethral stricture, and catarrhal inflammation of the kidney, the ureter, and the bladder are predisposing causes.

Symptoms.—In not a few cases the vesical symptoms are antedated by an attack of nephritic colic. Hence the necessity for cystoscopy after renal colic if no stone passed from the meatus, and the removal of any retained stone by the evacuator or the cystoscope. The severity of the symptoms of stone in the bladder depends more on the roughness of the stone than on its size. A small, rough calculus will produce intolerable anguish, whereas several large, smooth

stones will cause but moderate pain. A patient with stone in the bladder complains of frequency of micturition, particularly in the daytime, the desire being sudden, uncontrollable, and invoked or aggravated by exercise. This symptom is more positive in youth than in old age. Pain of a sharp, burning character is experienced at the end of micturition, due to the contraction of the empty bladder upon the stone or stones. It disappears gradually as urine enters and distends the bladder. The usual seat of this pain is the under surface of the head of the penis, a little behind the meatus, and the pain may continue for some time. By pulling on the penis to relieve this pain the prepuce of a child may become pendulous. The pain varies in severity, being much worse during an attack of cystitis and after exercise; it may be absent in encysted stone; it may be present early in a case, but almost disappear as a case progresses, and it is always worse in the young than in the old. Stone in chronic cases of atony and in cases of vesical paralysis causes neither marked pain nor frequency of micturition.[1] In a case of enlarged prostate pain *precedes* the act of micturition, in urethral stricture it *accompanies* it, and in stone, as already stated, it *follows* it (P. J. Freyer, in "The Practitioner," Feb., 1898). The symptoms may be somewhat confused by the coexistence of vesical calculus and prostatic hypertrophy. Attacks of cystitis in a man with calculus are spoken of as *attacks of stone*. When a stone is small, it may during micturition roll into the urethral orifice, and so cause a sudden interruption of the flow of urine, the stream again starting when the patient changes his position. This symptom is seldom met with and is particularly rare in the old, the stone in them dropping into the sac back of the prostate

Fig. 885.—Thompson's calculus sound.

and *below* the urethral orifice. Even if this symptom occurs, it is not conclusive, as a stalked tumor, a blood-clot, or a mass of pus or mucus may block the urethral orifice and cut off the stream. Hematuria may or may not be noted; it is most usual after exercise, and occurs at the end of the urinary act, the first urine passed being clear, the later urine being blood-tinged, and at the end of the act some drops of pure blood emerge. It is not one of the earliest symptoms. When it occurs it puts the patient in a great fright. It does not appear suddenly and profusely, but as gradual and trivial bleeding and with micturition. Blood appearing between acts of micturition comes from either the urethra or prostate (P. J. Freyer). The bleeding from a bladder tumor is profuse and the urine is mixed with blood and blood-clots and tumor fragments. Bleeding from a tuberculous ulcer of the bladder often resembles the bleeding caused by stone. Pus or mucopus will be observed if cystitis occurs with calculus disease. Priapism occurs in some cases. Pain of a reflex nature may be felt in the rectum, in the perineum, or in some distant part.

The above symptoms, even if all are present, do not prove that an individual has a stone in the bladder. To prove the presence of a stone the object must be pictured by the x-rays, seen through a cystoscope, or be touched by a sound. Simple touching by a sound is not sufficient, the contact must be felt and heard. To sound a patient, have the bladder well filled with boric acid solution or salt solution, and place him recumbent, with the knees drawn up. Never sound a person while he is standing, because of the danger of syncope. In an ordinary case

[1] "American Text-Book of Surgery."

in a male use a sound with a very slight curve (Fig. 885); in a man with hypertrophied prostate use a sound with a short and decided curve. The caliber of a stone-sound is No. 13 of the French scale. The instrument is carefully boiled and anointed with yellow liquid cosmolin. Examine the entire bladder systematically, and be sure a stone is present only when contact with the sound is both heard and felt. The stone may be difficult to find, or it may elude the instrument entirely when it is encysted, when it rests in a diverticulum, when it is fixed to the roof or anterior wall of the viscus, or when it is crusted with lymph or blood-clot. In doubtful cases always insist on a second examination, giving ether if the first was very painful. Occasionally, as Freyer pointed out in 1884, a small stone will be found by using a Bigelow evacuator, the current causing the calculus to knock against the tube. In many cases stone in the bladder may be detected by means of the *x*-rays (see Fig. 884). Use the cystoscope in all cases of suspected stone. If a stone is fixed in a diverticulum or projects from the ureter, or is in a sac back of the prostate, it may be missed by sound and evacuator tube, but be shown by the *x*-rays and the cystoscope. A stone, when it is detected, should always be measured by Thompson's instrument, an arrangement looking something like a small edition of a lithotrite, but having very delicate blades. The composition of the stone is assumed from an examination of fragments which pass by the urethra or which adhere to the measure. Remember that the outer layer of a calculus may be soft phosphate and the inner portion may be the harder uric acid, urate, or oxalate.

Stone in Females.—Calculus in the female is a rare complaint. In over 900 patients operated upon by Freyer for stone there were only 20 females. Pain and increased frequency of micturition, which are symptoms of stone in men and women, are in women commonly caused by other conditions, notably by uterine disease and displacement. A straight sound is used to examine a female for stone. If the surgeon is still uncertain after sounding, he uses a cystoscope or dilates the urethra and explores the bladder with his little finger.

Stone in children can occur at any age, and congenital cases have been placed on record. The uric-acid stone is most common. The symptoms are like those of the adult. The pain causes the male child to pull at the penis and the prepuce becomes pendulous. If in a child with stone the stream of urine is blocked from time to time, the child strains to empty the bladder, and after a time a hernia may form or prolapse of the rectum take place.

Treatment.—In people predisposed to stone (for instance, by lithemia) the physician should forsee the danger and antagonize it. Insist on the urine being kept dilute by the freest use of water and of milk, and reduce to a minimum the amount of alcohol, meat, sugar, and fat which is taken. Let the patient live chiefly on green vegetables, salads, bread, fruit, eggs, fish, poultry, weak tea or coffee, water, milk, and, if desired, a little red wine. Continued purging does harm by concentrating the urine, though a laxative may be employed when indicated. Moderate open-air exercise is of immense importance, sunshine and fresh air being Nature's correctives for a condition of imperfect oxidation power. If the urine be very acid, use piperazin, 15 to 20 gr. daily, liquor potassii citratis, phosphate of sodium, or borocitrate of magnesium. If the urine be phosphatic and alkaline, order mineral acids and strychnin, or, what seems to be very efficient, urotropin. Urotropin is given in 5-gr. capsules four times daily. If the urine be filled with oxalate, use the mineral acids with an occasional course of phosphate of sodium. Travel and rest at the seaside or at some spa are often of service in all forms. Always endeavor to prevent cystitis, and treat it promptly when it does occur. When a stone is once formed, it is an idle dream to think of dissolving it. An operation must be done. Some very small stones may be

crushed in view through the cystoscope by one of the several intravesical forceps, but in an immense majority of cases a very much more formidable operation is required. The operation selected depends upon the age, the state of the bladder and the prostate, the dilatability of the urethra, the kidney condition, the size and composition of the stone, and the number of calculi present (see Operations on the Bladder).

Bacteriuria.—Most urines contain bacteria. If bacilli are present in numbers, the condition is called *bacilluria.* The variety and number vary greatly in different individuals. In typhoid fever typhoid bacilli are found. In many cases of nephritis bacteria are present. In pulmonary tuberculosis, vesical tuberculosis, and renal tuberculosis bacilli may be found in the urine. In some cases numerous colon bacilli are found. They may seem to do no harm; they may cause nephritis; they may cause cystitis.

If a urine contains bacteria, inflammation of the genito-urinary tract may or may not exist, but even if it does not exist it is apt to occur at any time. In some persons the urine is found swarming with colon bacilli. Colon bacilli are capable of causing a very severe type of cystitis and nephritis. Bacterial urine explains many cases of urinary fever (see page 1369).

Cystitis.—Inflammation of the bladder is, as a rule, a complication of some other disease of the genito-urinary tract, but it may arise after exposure to cold and wet. Traumatism from a catheter, the presence of a stone, the spread of a urethral inflammation, pus infection, vesical tuberculosis or cancer, and the use of such drugs as cantharides, turpentine, alcohol, urotropin, and sandalwood oil in large doses may produce it. It appears not unusually during an exanthematous fever or in conditions of vesical paralysis; it often follows retention; frequently accompanies enlarged prostate and urethral stricture, and sometimes arises from concentration of urine or accompanies bladder growths. Acute cystitis causes discoloration and swelling of the bladder walls, and there is present a catarrhal discharge which is mixed with urinary elements, serum, mucus, often pus and epithelial débris. Ulceration, sloughing, or false-membrane formation may occur. Chronic cystitis is an inflammatory condition always due to bacteria. We frequently speak of a chronic cystitis as due to stone in the bladder, hypertrophy of the prostate gland, or tumor of the bladder. These conditions do not cause chronic cystitis, but act by rendering the bladder vulnerable to micro-organisms. Among the causative organisms we may mention the Bacillus coli communis, the gonococcus, the Bacillus tuberculosis, the Bacillus typhosus, the Urobacillus liquefaciens septicus, and the various pyogenic bacteria (Leonard Freeman). These bacteria may gain entrance on instruments or by way of the ureter, urethra, the lymph-vessels, and, in rare instances, by the blood.

In chronic cystitis there is an enormous production of thick, sticky mucus and the urine becomes alkaline. The excessive secretion of mucus and the great number of bacteria convert the urea into carbonate of ammonium, and this product, being irritant to the bladder walls, makes the inflammation worse. In chronic cystitis the bladder is contracted and has very thick walls, and the mucous membrane is thick, edematous, congested, and filled with large veins. The bladder may be ulcerated or encrusted with urinary salts. The urine contains bacteria, triple phosphate, pus, blood, and mucus, the blood emerging with the last drops of urine. Pyelitis may arise as a result of chronic cystitis.

What was formerly called inflammation of the neck of the bladder is an inflammation of the vesical trigone and of the posterior urethra. It is now usually called *urethrocystitis* or *trigonitis.*

Symptoms of Acute Cystitis.—Great frequency of micturition, with the passage, at each act, of a very small quantity of urine; the desire to urinate is

almost constant, and there is intensely painful straining (*tenesmus*). The pain is acute and scalding, and may be felt in the head of the penis, above the pubes or in the perineum; it often runs into the loins and the thighs and radiates over the sacrum. Pain above the pubes indicates involvement of the fundus, and pain in the perineum and in the head of the penis points to inflammation of the bladder trigone. The urine, at first clear, loses its transparency, becomes full of thick mucus, and often contains a little blood or pus. The patient not unusually has some fever. A rectal examination causes violent pain. If retention arises, there will probably be a chill and high fever, and anuria may occur.

Treatment.—In treating acute cystitis endeavor to remove the cause. By allaying an irritation or removing an obstruction the bladder will often become able to empty itself of retained urine, which urine causes congestion of the bladder and thus renders infection probable or may be itself filled with bacteria. If cystitis arises after the administration of cantharides, put the patient in bed and give him liquor potassii citratis. If it arises after the use of a clean sound, order rest in bed, suppositories of opium and belladonna, diluent drinks, and ammonii benzoas or lupulin. If the inflammation is septic (as from the use of a dirty sound) or is very acute, put the patient in bed, keep him warm, and use a hot sand-bag to the perineum and hot fomentations or poultices to the hypogastrium. Hot hip-baths may be used. The hips should be elevated, and the bowels should be emptied by the administration of salines and by glycerin enemata. An exclusive milk-diet is desirable. The patient should drink copiously of sweetened water containing a few drops of aromatic sulphuric acid or of milk of almonds. Sterilize the urine by the administration of urotropin, giving a capsule containing $7\frac{1}{2}$ gr. of the drug three times a day. Other remedies which may be of service in sterilizing the urine are quinin, boric acid, salol, borocitrate of magnesium, and salicylate of sodium. A valuable remedy consists of 15 gr. of salicylate of sodium and 15 gr. of benzoic acid, given three times a day in a little chloroform water. If the pain and straining still continue, order—

℞. Ext. hyoscyami.................................... gr. viij;
Ext. cannabis indicæ.................................... gr. viij;
Sacchar. alba.................................... gr. xlviij.—M.
Div. in pulv. No. xxiv.
Sig.—One powder every four hours.

Or,

℞. Camphoræ.................................... gr. viij;
Ext. cannabis indicæ.................................... gr. viij;
Sacchar. alba.................................... gr. xlviij.—M.
Div. in pulv. No. xx.
Sig.—One powder every three hours. (Von Zeissl.)

Suppositories of extract of belladonna are of great value. Suppositories each of which contains 1 gr. of ichthyol are of service, and one may be used every four hours. Opium, unfortunately, constipates; when it is given, secure evacuations by the use of glycerin suppositories, by the administration of saline cathartics, or by the employment of enemata. If opium is necessary, it is given in a suppository containing 1 gr. of powdered opium and $\frac{1}{6}$ gr. of the extract of belladonna every three or four hours. Hypodermatic injections of morphin may be required. Wash the bladder out daily with warm normal salt solution or warm boric acid solution. This can be done through a soft catheter or, better, by hydrostatic pressure. If retention occurs, use a soft catheter. If much blood is passed, give internally the tinctura ferri chloridi and blister the perineum. In urethrocystitis (trigonitis) the instillation of solutions of

nitrate of silver (5 to 10 gr. to the ounce) often do good. A very acute cystitis is rarely arrested within a week or ten days.

Symptoms of Chronic Cystitis.—This condition may be a legacy from acute cystitis or it may appear without any acute precursory phenomena. There will be found frequency of micturition, but not so great as in the acute form. There will be slight tenesmus and moderate pain from time to time, usually radiating toward the head of the penis. Constitutional symptoms may arise when kidney damage has become pronounced or sepsis has occurred from absorption. The urine is ammoniacal, fetid, and turbid; it is filled with viscid, tenacious mucus or with mucopus; it contains a great excess of phosphates, and occasionally clots of blood. The condition of chronic cystitis with the production of immense quantities of thick mucus is often called *chronic catarrh of the bladder.* Chronic cystitis may eventuate in the formation of stone or in the production of serious disease of the bladder, the ureters, and the kidneys. It is very apt to cause retention of urine.

Chronic Tuberculous Cystitis.—Chronic cystitis may be due to tuberculosis. Primary vesical tuberculosis is very uncommon. When it does occur it will often be found that it was preceded by gonorrheal infection of the bladder. Most cases of vesical tuberculosis are secondary to renal tuberculosis or to tuberculosis of the prostate, seminal vesicles, or epididymis. Some cases come on rapidly, many tubercle bacilli being found in the urine. Other cases come on more gradually, and in them the urine may contain few tubercle bacilli. In many such cases no tubercle bacilli are found. The tuberculous products caseate and ulcers form or fibrous organization takes place. A cystitis for which no cause can be found, and which is accompanied by pyuria and severe and lasting pain, is possibly tuberculous. Pyuria is usually present, but in some cases the urine is perfectly clear. In some cases the patient has painful paroxysms of varying duration and feels well between the atacks. Finding tuberculosis of the kidney, prestate, vesicle, or epididymis, increases the probability that tuberculous cystitis exists. The diagnosis is made by the cystoscope. Tuberculous ulceration is most common in the trigone and about the inner orifice of the urethra. A tuberculous ulcer is small. The adjacent mucous membrane is not inflamed, but contains grayish-white nodules (Louis E. Schmidt, "Jour. Amer. Med. Assoc.," July 19, 1902).

Treatment of Chronic Cystitis.—In treating chronic cystitis remove the cause, if possible (get rid of a stone, evacuate frequently residual urine, dilate a stricture, and remove a tumor). For chronic cystitis certain remedies are taken by the mouth. Water is drunk in large amounts, also iron spring-water (Marienbad, etc.). Salol and boric acid, 5 gr. of each four times a day, are very valuable. Salol in fluidextract of triticum repens does good; so does chlorate of potassium, 10 gr. daily. Either borocitrate of magnesium, quinin, or salicylate of sodium with benzoic acid may often be used with benefit. Alum, tannic acid, uva ursi, copaiba, cubebs, buchu, and turpentine have all been recommended, and possibly may be of some benefit. Urotropin is useful in many cases. This drug prevents the development of bacteria in the urine (Nicolaier) and antagonizes the tendency to sepsis and urinary poisoning. It is given in 5-gr. capsules, from four to six being given daily. Colon bacillus cystitis is treated by giving sodium benzoate and urotropin internally. In obstinate cases a vaccine should be made and given. In cases of chronic cystitis (even the tuberculous form) Stellwagen has had excellent results from the following capsule: 3 min. of creosote, 6 min. of oil of sandalwood, 1 min. of oil of cinnamon, 1 gr. of pepsin. One capsule after each meal. Whatever remedy is used, see that the bowels move once a day and that the skin is active. Champagne and beer must be avoided. If residual urine gathers, a soft

catheter must be regularly employed. If it is possible to introduce a catheter of considerable size, catheterization may be all that is needed in the case. In some cases of chronic cystitis the retention of a catheter from three to five weeks is of the greatest service. If the case is very severe, the bladder must be washed out daily with peroxid of hydrogen (25 to 40 per cent. solution), nitrate of silver (1 : 8000), boric acid (5 to 10 per cent.), carbolic acid (1 : 500), corrosive sublimate (from 1 : 20,000 to 1 : 5000), or permanganate of potassium (1 : 4000). If nitrate of silver or permanganate of potassium is used, first rinse out the bladder with distilled water. If any other agent is used, first wash out the bladder with either boiled water or normal salt solution. The daily injection of a 2 per cent. solution of ichthyol may prove useful. Collin uses a 1 per cent. solution of guaiacol carbonate in sterile olive oil. Some surgeons occasionally employ, at intervals of a number of days, strong silver solutions (30 or 40 gr. to the ounce). If a strong solution is used, after the drug flows away wash out the bladder with a solution of common salt. The bladder is usually washed out by attaching to the free end of a soft catheter, the other end of which is in the bladder, a tube which is connected with a graduated bottle, the force being obtained by elevating the reservoir (*fountain irrigation*). The bladder can be irrigated without using a catheter, the resistance of the compressor muscle of the urethra being overcome by the pressure of a column of water. The reservoir is raised to the height of 6 feet. The patient sits in a chair. The tube of the reservoir has upon it a clamp to control the flow, and in its end a large bulbous tip which will fill the meatus (Valentine's instrument). The tip is inserted into the urethra, the clamp on the tube is loosened, and the patient is directed to take a deep inspiration. In a short time the bladder fills with water, the tube is removed, and the patient empties the viscus naturally. In some cases it is necessary to wait quite a while for the column of water to tire out the muscle. If the fluid will not enter, direct the patient to make efforts as in micturating, the pressure of the fluid on the anterior surface of the cut off muscles being kept up. If this fails, direct him to urinate, and then the surgeon makes another attempt to get the fluid to enter. After a little practice a patient learns how to admit the fluid.

If the cystoscope discloses tuberculosis of the bladder and there is known to be tuberculosis of one kidney, cure of the bladder is impossible without preliminary nephrectomy. In tuberculous cystitis collargol may be injected once a day. A 1 per cent. solution is used and it is allowed to remain for a long time. The method is painless. Collin advises the instillation of 30 min. of the following mixture into the bladder and posterior urethra: 5 gm. of guaiacol, 1 gm. of iodoform, 100 gm. of sterile olive oil. About 30 min. of this are injected once a day. Rovsing, of Copenhagen (Meeting of French Urological Assoc. of 1910), uses, in tuberculosis of the bladder, a fresh solution of carbolic acid (3 to 6 per cent.). He injects from 25 to 50 c.c. through a catheter, allows it to remain in the viscus for two or three minutes, lets it run out, and repeats this procedure until the fluid emerges clear. This treatment is carried out at first every other day. When, on the intervening day, the urine remains clear the interval between treatments is lengthened. Rovsing claims to have cured 28 cases in from four to six weeks. During treatment he makes a cystoscopic examintion every other week to determine the progress of the case. The injections are usually very painful and would be intolerable without a preliminary injection of a local anesthetic (25 c.c. of a 1 per cent. solution of eucain). Sometimes, in tuberculous ulceration of the bladder, curetting through a cystoscope is useful. In other cases the bladder must be opened, the ulcer curetted, and the viscus drained.

If the ordinary methods of treatment fail to cure chronic cystitis; if the bladder resents catheterization and irrigation; if in spite of irrigation the

urine does not become clear; and if there are evidences of infection of the patient and breaking down of his general health, drain by perineal or suprapubic cystotomy and through the incision wash the bladder frequently and thoroughly. If a persisitent cystitis is due to stricture which dilatation fails to cure, perform external perineal urethrotomy and employ perineal drainage.

Ulcer of the bladder may be due to injury, cystitis, tuberculosis, malignant tumor, or gonorrhea. A form of ulceration particularly common in anemic women is a solitary, punched-out ulcer (Louis E. Schmidt, "Jour. Amer. Med. Assoc.," July 19, 1902). Ulcers may be single or multiple. Perforation may occur.

A perforation may occur into the peritoneal cavity or into the perivesical cellular tissue. In the former case, after the onset of marked hematuria, there are shock, abdominal pain, and peritonitis. In the latter case there is extravasation of urine or abscess formation.

Tuberculous ulcer is discussed on page 1327 and cystoscopic ulcer on page 1301.

Schmidt (Ibid.) points out that gonorrheal ulceration is apt to be multiple, and causes severe pain and bloody, turbid urine. As a rule, when the bladder is ulcerated, the urine contains blood, blood-clots, or tissue débris, but the urine may be clear when there is a tuberculous ulcer or solitary ulcer.

Diagnosis is usually made by the cystoscope. In some cases it is made by exploratory suprapubic incision.

Treatment.—If there is one ulcer, or if there are a few ulcers, curet through an operating cystoscope, use irrigations, and keep the urine aseptic. In widespread ulceration perform suprapubic cystotomy, curet the diseased mucous membrane, and insert a drainage-tube. In some cases of malignant growth the cautery is used as a palliative measure. Perforation is treated as is rupture of the bladder (see page 1318).

Tumors of the Bladder.—These growths are usually said to be very rare, but in Guyon's statistics they are found to constitute 3.9 per cent. of all cases of genito-urinary disease. They are almost 5 times as common in males as in females. They are most frequently met with between the ages of fifty and sixty, although myxoma is met with only in childhood and sarcoma is most common in the young (Lincoln Davis, in "Annals of Surgery," April, 1906). Persistent vesical irritation may, perhaps, be an element in causing tumor. Tumors of the bladder may be either innocent or malignant, the latter being the commonest. Innocent tumors which may arise from the bladder are papillomata or villous tumors, adenomata, mucous polypi (myxomata), fibrous polypi, myomata, and angiomata. A myoma may attain a great size (even that of a child's head). The common form is intravesical. There is an interstitial form and a peripheral form. Papilloma is far and away the most common form of innocent tumor. Cysts may also arise. Malignant tumors are sarcoma (comparatively rare) and carcinoma (encephaloid, rare; epithelioma, common). Munwes ("Zeit. f. Urology," Nov., 1910) collected 107 cases of sarcoma. Sarcoma begins in the submucosa. The majority of bladder carcinomata are secondary to growths of the rectum, prostate, or uterus. Adenocarcinoma and scirrhous carcinoma are practically always secondary to rectal, prostatic, or uterine tumors. Papillary cancer and epithelioma are not unusually primary (Mandlebaum, in "Surg., Gynecol., and Obstet.," 1907). Primary carcinoma, like primary sarcoma, most commonly arises in or near the trigone. Any tumor of the bladder, innocent or malignant, will eventually cause death if allowed to remain. Papilloma is very apt to become cancerous.

Symptoms.—The innocent tumors rarely cause cystitis or irritation, though by obstructing the ureters or the urethra they may induce disease of the kidneys. Hematuria is almost invariable present at some time during the

existence of a bladder tumor. It is apt to be profuse, and the urine contains blood, blood-clots, and perhaps fragments of tumor. The bleeding is intermittent, may occur even when the patient is at rest, and, except in malignant disease, is seldom preceded or accompanied by pain. Bleeding usually occurs at the termination of micturition, the first urine being clear and the last red or clotted. Often hemorrhage is the only phenomenon produced by a papilloma or a mucous polypus. Hemorrhage may occur from a myoma. Malignant tumors cause cystitis, and the urine contains mucus, blood, and pus. The growth may become crusted with salts from the urine. Cancer is decidedly and often horribly painful. In malignant disease the rectum usually becomes involved. Hydronephrosis may be caused. Metastases to the lungs are common. Ulceration may occur into the peritoneal cavity or rectum. A malignant tumor progresses much more rapidly than an innocent growth, although in vesical cancer metastases are not formed so early as in some other regions. Innocent tumors are felt with difficulty with the sound, but malignant tumors are easily felt. In some cases a tumor can be detected by a bimanual examination (a finger in the rectum and the fingers of the other hand on the abdomen). Make a careful study to determine whether or not a growth has infiltrated the prostate, the seminal vesicles, the rectum, or the perivesical tissues. Bleeding follows the use of a sound. There may be difficulty in starting the stream in micturition, there may be interruption or irregular halts in the stream. The latter condition is called *stammering of the bladder*. The urine should be examined microscopically to see if it contains villi, portions of fibroma, colonies of cancer-cells, or fragments of epithelioma. A cystoscope should be employed in order to reach a diagnosis. If the urethra is too narrow for the cystoscope, this channel must be dilated. If there is profuse bleeding an irrigating cystoscope must be employed. In doubtful cases exploratory suprapubic cystotomy is advisable.

Treatment.—Some innocent tumors may be cured by fulguration. Papillomata are particularly amenable to this treatment. Recurrence is rare. Some innocent tumors (for instance, peripheral myomata) are treated by suprapubic incision and removal of the growth and a portion of the bladder wall. A papilloma which recurs after fulguration should be treated by excision with a portion of the mucous membrane and submucous tissue of the bladder wall. The perineal operation only enables the surgeon to reach and remove growths of small size, pedunculated growths, and growths near the neck of the bladder. (See Operations on the Bladder.)

Among the operations practised for malignant disease are *partial cystectomy* with resection of one or both ureters, partial resection of the bladder wall, removal of the growth without resection of the wall (a useless procedure), curetting (which is futile). Complete extirpation of the bladder (*total cystectomy*) for cancer has been performed by Bardenheuer, Heresco, and others. Goldenberg reported 26 cases, with a mortality of over 60 per cent. It is usually done in two stages, in the first operation the ureters of a man being transplanted into the rectum, the ureters of a woman into the rectum or vagina. About three weeks later the bladder is removed. The adjacent lymph-nodes along the internal iliac vessels and in front of the sacrum must be removed in all cases. The surgeon should bear in mind that vesical scirrhus and adenocarcinoma are practically always secondary growths, and if he cannot remove the primary growth he should not extirpate the bladder. The complete procedure has been carried out successfully at one operation (Tuffier and Dujarier, "Rev. de Chir.," April, 1898). Some surgeons prefer preliminary double lumbar nephrostomy; others transplant the ureters to the skin surface. The operation of complete extirpation is of questionable value. In most cases it has proved a fatal failure. Munwes ("Zeit. f. Urology," Nov., 1910) re-

ported 69 radical operations for sarcoma. Only 3 patients lived for more than a brief time.

In Rafin's collection of 30 cases of cancer there were 17 deaths. One case was alive five years after operation, 1 fifteen months, and 1 seven months after. Watson's table of 25 cases of cancer shows 14 deaths and only 2 of the survivors were alive and free from recurrence after three years.

Complete extirpation should be employed only when cancer involves the bladder extensively. I agree with Berg ("Annals of Surgery," Sept., 1908), that if less than one-third of the bladder is involved the operation should be partial cystectomy with implantation of the ureters into the portion of bladder remaining. The surgeon removes the anatomically related lymphatic area and always bears in mind that vesical adenocarcinoma and scirrhus are secondary growths. Partial cystectomy saves the performance of the fatal operation of transplanting the ureters as is ordinarily done, or the questionable operation of lumbar nephrostomy with all of its unpleasant consequences. In Rafin's collection of 96 cases there were 21 deaths (a mortality one-half that of complete cystectomy); 50 cases were traced—5 were well over three years and 16 over six months (Berg, Ibid.). Henry Morris lays down the following rule: "When an infiltrating growth is felt, *per rectum* or *per vaginam*, or with the sound, to be involving a large surface of the bladder wall, to be infiltrating its coats, especially in the neighborhood of the ureters and neck of the bladder, no operation whatever should be proposed unless the hemorrhage is copious or the symptoms of cystitis severe, and then an incision for palliative purposes only should be made" (Treves's "System of Surgery").

Many surgeons content themselves in vesical cancer with suprapubic cystotomy, removing the growth and a portion of the bladder wall. If removal is not possible, they curet, cauterize, and drain.

Operations On the Bladder.—Lateral Lithotomy.—*Lithotomy* is the removal of a stone from the bladder. *Lateral lithotomy* is an operation which was once a glory of surgery, which is every year becoming less popular, but which is still at times employed by surgeons, especially for stone in children. This operation should not be performed if the stone is over 2 inches in its short diameter; it is rarely justifiable if the stone weighs 3 oz. or more (Cage); and it must not be performed for encysted stone, or on a person with a deep perineum, a narrow pelvic outlet, or an enlarged prostate. For one week before the operation keep the patient in bed, wash out the bladder daily with hot boric acid solution, and administer salol and boric acid by the mouth, 5 gr. of each four times a day. The night before the operation give a saline, order a hot bath, and have the perineum, the scrotum, the buttocks, and the inner sides of the thighs cleansed and dressed antiseptically. In the morning an enema is to be given. At the time of operation the bladder should contain several ounces of boric acid solution. The instruments required are a lithotomy knife, a straight probe-pointed bistoury, a grooved staff, a stone-sound, stone-forceps and scoops, a tenaculum, an aneurysm needle, a fountain-syringe, curved needles and a needle-holder, hemostatic forceps, a tube with chemise (see Fig. 229), a Paquelin cautery, a Clover crutch, and a lithotrite.

Place the patient upon his back, anesthetize him, and find the stone by sounding. If the stone is not discovered by the sound at that time, *do not operate.* Place the buttocks so that they project beyond the edge of the table, introduce the staff into the bladder, flex the legs and thighs, and fasten the patient in the lithotomy position with a crutch. During the first incision the handle of the staff is held toward the belly; after the first cut the staff is set perpendicularly and is hooked up under the pubes. An incision is made, starting just to the left of the raphé of the perineum and $1\frac{1}{4}$ inches in front of the edge of the

anus, and passing downward and outward to between the anus and the ischial tuberosity, but one-third nearer the former than the latter. In the adult this incision is 3 inches in length. The first incision is superficial and does not reach the staff, but it is this incision which may cut the rectum. After making the first cut the nail of the left index-finger feels for the groove of the staff, the staff is hooked up, the knife is entered into the groove and is pushed into the bladder, and as it is withdrawn the wound is enlarged. As the knife enters the bladder there is a gush of fluid. The finger follows the knife and stretches the wound, the staff is withdrawn, and the stone is felt for and extracted with forceps. Liston showed years ago the value of keeping the finger in the wound. This maneuver retains some water in the bladder, and as a consequence causes the stone to rest at the lowest part of the viscus, and when the forceps are introduced they at once come upon the stone. In withdrawing the stone make traction in the axis of the pelvis, and do not rotate the calculus until it is entirely out of the prostatic urethra. Wash or scrape away débris or incrustation from the wall of the bladder, see that no other stone is present, syringe out the viscus with warm salt solution, insert a tube, apply antiseptic dressings around the tube, and put on a T-bandage. The end of the tube which is external to the dressings is fastened to the tails of the T-bandage. A rubber cloth is put on the bed, under the body and legs, and the patient's buttocks rest upon a mass of old linen, the scrotum being raised on a pad. The knees are bent over pillows. Change the linen as soon as it becomes wet. Remove the tube in forty-eight hours. The urine begins to come by the urethra from the eighth to the twelfth day. In children the incision is not so long, it is dilated by forceps instead of by the finger, and no tube is required. In lateral lithotomy the prostatic and membranous portions of the urethra are opened, the prostate gland is partly divided by the knife, and the wound is dilated by the finger. One objection to the operation is that it is possible to cut the rectum, and another is that inflammation may occlude the ejaculatory ducts and cause sterility.

Suprapubic Lithotomy.—This operation is the removal of a stone through an opening above the pubes. It is in many instances the preferable operation. The mortality of this operation is higher in children than that of lateral lithotomy; in adults and in individuals beyond middle life the mortality is decidedly less than is that following the lateral operation. It is used for the removal of multiple calculi, for very hard stones, for stones above 2 inches in their short diameter, for calculi in men with enlargement of the prostate, for foreign bodies incrusted with sediment, when the perineum is deep, when the pelvic outlet is narrow, for encysted stones, for calculi associated with a vesical tumor, and when the urethra will not permit the use of a lithotrite. Before doing the operation determine the carrying capacity of the bladder when the patient is not anesthetized. This gives the safe limit of distention. Under an anesthetic the bladder will receive 3 or 4 more ounces than the safe amount. The patient is prepared as for lateral lithotomy, except that the pubes are shaved, and the lower part of the abdomen and the upper part of the thighs are disinfected. During the operation the penis is kept wrapped in a piece of antiseptic gauze.

In performing the operation place the patient in the Trendelenburg position. It is necessary to distend the bladder and raise it in order to have the prevesical space uncovered by peritoneum. In most cases this is accomplished by distention of the bladder and the Trendelenburg position. In a few cases in which the bladder holds very little fluid a rectal bag is used to lift the bladder. If a rectal bag is to be used an assistant oils it and pushes it (empty) above the sphincters. It is filled after the bladder has been injected. Draw off the urine with a soft catheter, wash out the bladder with a solution of

silver nitrate (1 : 8000 to 1 : 5000), and inject the bladder with the same solution. In a child under the age of five inject 3 to 4 oz.; in an adult it is usual to inject 10 to 12 oz. Withdraw the catheter and tie a tube around the penis to prevent the escape of fluid. After injecting the bladder with fluid, if the viscus is not well lifted, inject the rectal bag with water and clamp its tube with forceps. In a child inject from 2 to 4 oz. of warm water into the rectal bag; in an adult inject 10 oz. Bristow suggested the injection of air into the bladder. Some surgeons simply inject air by means of a catheter and a brass syringe or a Davidson syringe. Air injection is not recommended if fluid can be used. In operating on an air-distended bladder there is greater danger of trauma, shock, and postoperative bleeding. If air is injected, a rectal bag is never used, and the patient is placed on his back rather than in the position of Trendelenburg. The best method of injecting air is that of F. Tilden Brown,[1] by means of a bicycle pump. A catheter is introduced, the bladder is washed out, the catheter is fastened to a bandage, the bicycle pump is attached, the operation is proceeded with, and when the transversalis fascia is exposed the bladder is filled with air, the soft catheter is clamped, and the bladder is opened. Make a 3-inch longitudinal incision in the median line of the hypogastric region, terminating over the symphysis. When the prevesical connective tissue is reached push it up with a gauze-covered finger. In close association with this tissue are the prevesical fat and peritoneum. The pushing up must be done slowly and gently with a sweeping motion. Any roughness may be responsible for disaster. If the peritoneum should appear, push it up. Hold the wound edges apart by retractors. The large veins are seen, giving the bladder a blue color. Avoid these veins if possible, but even if they should be cut bleeding will usually cease when the bladder has been opened and the rectal bag has been emptied and removed.

Fig. 886.—Cathcart drainage. The Y-tube is of glass and is darkened in order to be shown against a white background.

Clamp bleeding vessels. Pass a stay suture of strong silk on each side of the contemplated incision in the bladder. Catch each suture by a hemostat and let it hang. Open the viscus in the middle line above, and cut toward the pubes. Explore the bladder, remove the stone or stones, scrape away incrustations, ligate bleeding vessels outside the bladder, and irrigate the viscus with hot saline solution. Introduce a double tube into the bladder, and attach to its external end a long tube to siphon off the urine. The bladder can be drained very satisfactorily by a siphonage apparatus (Fig. 886). Suture the muscles and fascia at the upper part of the wound. Dress with dry antiseptic gauze and a rubber-dam, the dressings and binder being split to go around the tube. Catch the urine which siphons over in a bottle containing some antiseptic fluid. Change the dressings as often as they become wet.

[1] "Annals of Surgery," Feb., 1897.

Take out the tube in four or five days, and allow the wound to heal by granulation. The patient may get up in two weeks. Many Continental surgeons advocate immediate suture of the bladder after incision. Albert, Vincent, Bassini, DeVlaccos, and others advocate immediate suture. The suture material should be catgut. After suturing a catheter is kept in the bladder to drain the viscus. Immediate suture may be employed in patients of any age, but should not be used if the urine is very septic or if pyelonephritis exists. In some cases the attempted closure will fail; in others it will only partially succeed; in others it will prove successful; but even if it only partially succeeds it will tend to prevent dissemination of urine in the prevesical cellular tissue. The chief causes of death after suprapubic lithotomy are septicemia, secondary hemorrhage, cellulitis, peritonitis, and suppression of urine. J. W. White estimates the relative mortality of suprapubic and lateral lithotomy as follows: In children the suprapubic operation gives a mortality of 12 per cent.; the perineal, of 3 per cent. In adults the suprapubic gives a mortality of 12 per cent.; the perineal, from 8 to 12 per cent. In old men the suprapubic gives a mortality of 25 to 30 per cent.; the perineal, 30 to 40 per cent.

Crushing of Vesical Calculi.—This is now done in one sitting, the old operation of Civiale, which required repeated crushings, being obsolete. In every case of suspected stone (as before stated) the cystoscope should be used.

Contra-indications to Litholapaxy.—Papilloma, malignant tumor, projecting prostatic lobes, encysted stone, and diverticuli.

Litholapaxy (*Bigelow's operation*, or *rapid lithotrity*) is the operation for removing a stone from the bladder in one sitting by thoroughly crushing the stone and completely washing away the fragments. This operation is wonderfully successful if done by an expert. Few of us do it sufficiently often to learn how to perform it with great rapidity, certainty, and safety. It is the best operation in most cases if performed by a very skilful man. It is the operation in the majority of cases for even the general surgeon to select, but the general surgeon will have better results in certain difficult cases after suprapubic lithotomy than after litholapaxy. Sir H. Thompson says this method is suited to 29 cases out of 30. Litholapaxy should be employed if the bladder will hold at least 4 oz. of fluid and is in a fairly healthy condition; if the urethra is tolerant and penetrable by instruments; if the stone is not too hard, does not weigh over $2\frac{1}{4}$ oz., and is not over 2 inches in diameter. It is not suitable for multiple calculi, for large and hard calculi, for encysted stones, or for a patient with marked enlargement of the prostate gland, with vesical atony, or with cystitis. An easily dilatable stricture need not prevent the surgeon doing litholapaxy. The stricture can first be dilated, and later Bigelow's operation can be performed, but firm, gristly strictures demand a cutting operation. If the urethra is intolerant to instrumentation, the patient being prone to febrile attacks when it is attempted, cut instead of crushing. An individual laboring under kidney disease will do better after this operation than after cutting (Cage). In diabetes, locomotor ataxia, and conditions of exhaustion patients are best treated by Bigelow's operation, unless cystitis exists.

The Indian surgeons have had the most admirable results from litholapaxy. It has often been claimed that such results were due to racial peculiarities of the patients and various factors regarding their habits, diet, etc. The fact, however, that some of these very surgeons have returned to England and repeated their triumphs in London shows how large a part masterly dexterity played in obtaining success.

J. A. Cunningham ("Brit. Med. Jour.," Aug. 7, 1887) reports upon 10,073 Indian cases of litholapaxy. The mortality was 3.96 per cent.

Cabot, of Boston, in 116 cases had but 4 deaths, and 2 of these were due to pneumonia.

The preparation cf the bladder is the same as for lithotomy. Be sure to measure the stone, and to ascertain also whether a lithotrite can readily be introduced and manipulated. The instruments required are a stone-sound (see Fig. 885), lithotrites (several sizes, Figs. 887–889), an evacuating bulb and tubes (straight and curved, Figs. 890, 891), soft catheters, a glass irrigator to inject the bladder, and instruments in case the surgeon is forced to cut. The patient is anesthetized and is placed upon his back, a pillow is inserted under the pelvis, and he is well wrapped up. The urine is drawn and a measured amount of warm boric acid is allowed to flow into the bladder. This plan is better than having the patient retain his urine, as in the latter case there is no certainty as to the amount of fluid in the viscus. It is well to introduce at least 5 or 6 oz. of fluid, if possible. If the bladder will not hold 4 oz. the operation is unsafe (Thompson). The lithotrite, preferably the instrument of Forbes (Fig. 889), is now introduced,

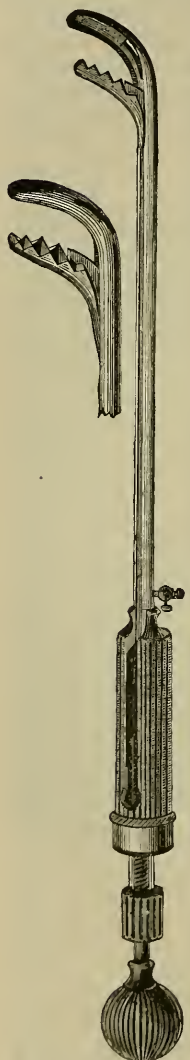

Fig. 887.—Bigelow's lithotrite.

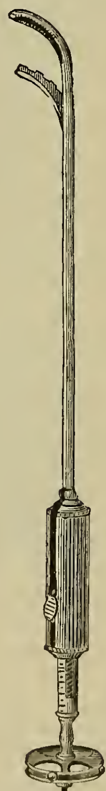

Fig. 888.—Thompson's lithotrite.

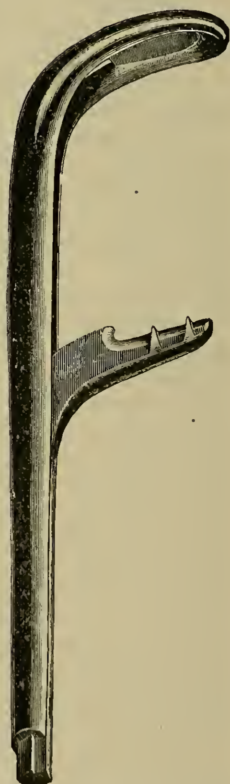

Fig. 889.—Forbes's lithotrite.

the handle being gradually raised to a vertical position as the penis is drawn up on the shaft, but not being depressed until the instrument has passed by its own weight into the prostatic urethra. Thompson's plan for catching the stone is as follows: After introducing the lithotrite, let its lower end rest for a few seconds on the bottom of the bladder, so that currents will subside; then draw back the male blade, wait a moment, close the blades, and in almost every

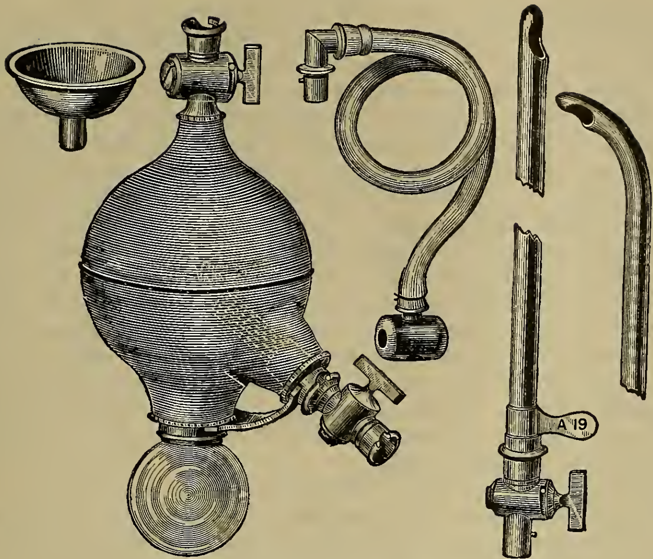

Fig. 890.—Bigelow's latest evacuator.

instance the stone will be caught. If the stone is caught, press firmly to see that the calculus is well held, lock the instrument, and break the foreign body by screwing. When resistance suddenly ceases the stone has either slipped or has been crushed; if crushed, the blades should have been felt forcing through the stone and the calculus should have been heard to break. When resistance ceases catch and crush again as above directed. Rapid movements with the lithotrite are improper, as they establish currents which are apt to push away the stone. If the above maneuver does not catch the stone, see if the calculus be near the neck of the bladder. Pull the instrument close to the vesical neck, and open it, not by pulling the male blade, but by pushing the female blade. If the operator still fails to catch the stone, or if, after crushing, a large fragment knocks against the evacuator, which fragment cannot pass, conduct a careful search: turn the blades to the right side, open, and close; then to the left side, open, and close; next turn the point around behind the prostate, open, and close. After catching a stone with the lithotrite, turn the instrument very slowly, so as to detect the catching of the bladder wall if it has occurred, and crush the stone in the middle of the bladder with the blades up. After crushing several times, proceed to evacuate. Fill the aspirator with warm saline fluid. Insert an evacuating catheter, its point being in the center of the bladder, let the fluid and fragments run out, and attach the aspirator to the

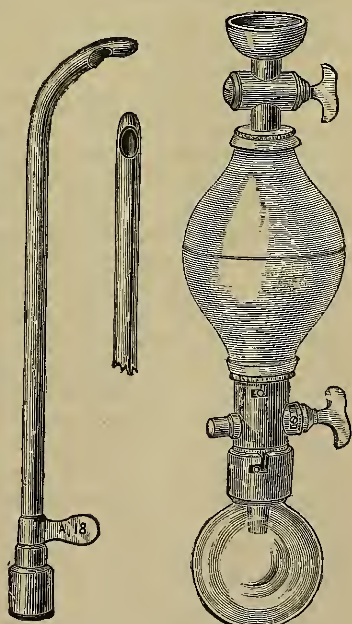

Fig. 891.—Thompson's evacuator.

catheter; turn the valve, and compress and relax the bulb so that an ounce or more of fluid is forced in at each squeeze, the compression coinciding with expiration. The débris falls into a bulb, and the pumping is continued until the fragments cease to pass, whereupon the point of the catheter is pushed against the floor of the bladder and another trial is made. If fragments which cannot gain exit are felt knocking against the tube, withdraw the evacuator, crush again, and again use the aspirator. When no more débris comes away and no more fragments are felt, withdraw the tube and carefully sound the bladder. Keyes advises the operator to seek for a final fragment by listening with a stethoscope while pumping at the bulb and searching the bladder with the tube. The amount of blood usually obscures a cystoscopic view. This operation will rarely occupy over forty minutes, though Bigelow has protracted it for three hours, the patient recovering. A serious complication is severe bleeding, due to damage done with the instrument or to the presence of a tumor which easily bleeds. The injection of moderately hot water or of adrenalin solution (1 : 10,000) usually checks hemorrhage, but if bleeding is dangerous in amount the operation of litholapaxy should be abandoned and suprapubic lithotomy be performed.

If clogging of the lithotrite with fragments occurs, forcible pushing of the blades together repeatedly will probably amend it; but it will never happen if the surgeon uses a proper form of instrument. A lithotrite with a fenestrated blade will not lock. Forbes's lithotrite is a very powerful instrument, the blades of which will not lock. If the blades of a lithotrite should become forcibly and hopelessly locked, make a perineal section, clear out the blades, close them, and then withdraw the instrument.

After-treatment.—Put the patient to bed, apply a bag of hot water to the hypogastrium, and give him a hypodermatic injection of morphin as he recovers from ether. Give a hot hip-bath every night, and administer liquor potassii citratis in moderate doses every day. If urethral fever occurs, use quinin and morphin, wash out the bladder several times daily with warm boric acid solution, and tie in a rubber catheter. If retention occurs, use the catheter. If cystitis appears, treat as in an ordinary case. The urine ceases to be bloody in two or three days, and the patient may get up in a week. Before the case is discharged cystoscopy should be practised to be certain that no fragments of stone remain.

Litholapaxy in Male Children.—It used to be the teaching that a child, because of the small size of the bladder, the small diameter of the urethra, and the readiness with which the mucous membrane is lacerated by even slight violence, is a poor subject for crushing. Lateral lithotomy is known to be eminently successful when performed upon children. The elder Gross did this operation upon 72 children, with only 2 deaths. Keegan, however, has persuaded the profession that rapid lithotrity is perfectly applicable to children: He shows that the bladder of a child of even less than two years of age is quite large enough to allow the surgeon to manipulate an instrument; that the mucous membrane is in no danger if the operator is careful, and that the urethra is by no means so small as was supposed. The urinary meatus must often be incised, and after doing this, Keegan states, there can be passed in a boy of from three to six years a No. 7 or 8 lithotrite (English), and in a boy of from eight to ten years a No. 10 or even a No. 14. It is, however, just to state that the operation is more delicate than a like procedure on older persons, and that no one is justified in doing it who has not had considerable experience in adult cases. Furthermore, it should be noted that Keegan's mortality by this operation has been 4.3 per cent., while Gross's mortality from lateral lithotomy on children was under 3 per cent.

Special points relating to litholapaxy on male children are as follows: use well-

fenestrated lithotrites; have a stylet to punch out the fragments blocking the evacuator; and crush the stone to a fine mass. There can usually be employed a No. 8 lithotrite and a No. 8 evacuating tube (English scale).

Perineal Lithotrity (*Keith's Operation*).—This operation is employed by some surgeons in dealing with very hard or very large calculi in male adults, or in cases in which it is impossible to introduce a lithotrite into the bladder. Keith's operation consists in opening the urethra from the perineum, passing a lithotrite through the wound, into the urethra and along the urethra into the bladder, and crushing the stone, introducing an evacuator and removing the fragments. In Keith's operation the incision is median and opens the membranous urethra. In very large stones Milton thinks the surgeon should open the bladder as in ordinary lateral lithotomy, introduce a lithotrite through the incision, and crush the stone before extracting it, thus avoiding the infliction of injury upon important structures.

Operation for Stone in Women.—If the stone be small, give the patient ether, place her in the lithotomy position, dilate the urethra by the uterine dilator until it admits the index-finger, and remove the stone by the finger, the scoop, or the forceps. If the stone is found to be too large to pass, crush it by a lithotrite and get rid of the débris by the evacuator. Large stones (2 oz.) may require suprapubic lithotomy. Vaginal lithotomy is never required. If done, it is very likely to leave as a legacy a vesicovaginal fistula. In female children dilate the urethra, crush the stone, and evacuate.

Cystotomy or Cystostomy.—These terms mean the opening of the bladder. If the opening is made for diagnosis or treatment and is then closed or allowed to close, the operation is a cystotomy. If the wound is deliberately kept open it is a cystostomy. The bladder may be opened for drainage, for diagnosis, for the removal of stones or tumors, or for the treatment of ulcers. This opening may be done by (1) a suprapubic cut (as in suprapubic lithotomy), (2) a lateral perineal cut (as in lateral lithotomy), or (3) a median perineal cut (as in median lithotomy).

The operation may be completed in one sitting, or the bladder may be only exposed, the opening of it being delayed for several days until it becomes adherent to the margins of the wound (Senn's operation). Senn's operation prevents infiltration of urine into the prevesical space, and it is advisable to select it if the urine is very foul.

A sinus may persist after suprapubic cystotomy, but usually the wound heals unless it is kept open by some expedient.

The effects of suprapubic drainage are very beneficial in cases of chronic cystitis associated with hypertrophy of the prostate gland, the urine being foul. Drainage causes the urine to become clear and the mucous membrane of the bladder to become normal. If the opening is made as a permanent drain, there will usually be incontinence, as the new channel has no sphincter action (Dandridge). Figures 895 and 896 show tubes for prolonged drainage.

Suprapubic Cystotomy (or Cystostomy).—The operation is employed to allow the surgeon to explore the bladder, to treat an ulcer, to provide drainage, or to remove a tumor. If the operation is for calculi, it is known as suprapubic lithotomy (see page 1331). After the bladder is opened its interior can be illuminated by the rays of an electric lamp, which appliance is fastened with a mirror to the forehead of the operator. If an ulcer is found, it is scraped with a curet or a spoon. Most cases of tumor require suprapubic cystotomy. It is true that a small single growth at the vesical neck is accessible by median cystotomy, but the area for manipulation is very narrow and the growth cannot be seen. Every large growth, all cases of multiple tumors, and all cases of tumor in individuals with great depth of perineum or with enlarged prostate require suprapubic cystotomy, an operation which allows one to feel and to

see the growth, which gives room for manipulation, and which permits thorough exploration of the entire bladder. The patient is put in the Trendelenburg position if water distention is used, but is placed horizontally if air distention is employed. After opening the bladder as for stone (see page 1332), hold the edges of the incision apart by means of a speculum (speculum of Keen or Watson) or by retractors, and reflect the electric light into the wound. Growths when seen can be twisted off, a pair of forceps holding the base and another pair being used to twist, but after removal by twisting they will always recur unless the base and the mucous membrane about the base is removed. Broad malignant growths may require partial cystectomy. Some growths (as inoperable cancer) are removed piece by piece with Thompson's forceps (Figs. 892–894), the base of the tumor being scraped. Such a procedure is merely palliative. Soft growths are scraped away by a curet, a spoon, or the finger-nail. If bleeding is severe, check it by pressure, by hot water, by a 1 : 10,000

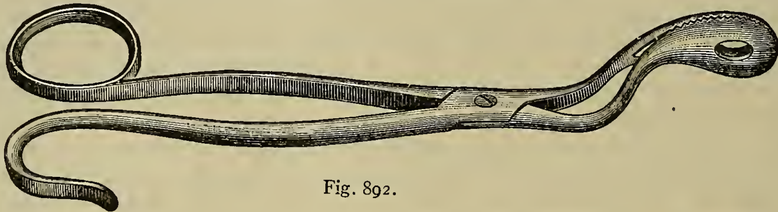

Fig. 892.

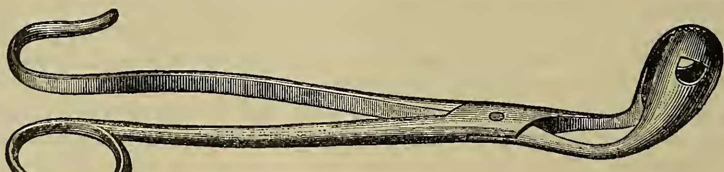

Fig. 893.

solution of adrenalin chlorid, or even by the actual cautery. In some cases the wound is allowed to heal rapidly. In others the bladder is drained for a considerable time. In some it is kept open permanently. Permanent drainage is desirable in some cases of enlarged prostate, and in such cases Senn's tube (Figs. 895 and 897) or Stevenson's tube (Figs. 896 and 898) may be employed.

Median Cystotomy (or Cystostomy).—The same incision is made in the perineal raphé for median cystotomy as for median lithotomy. A grooved staff is introduced and is hooked up under the pubes; an incision is made into the membranous urethra, and is extended backward for ¾ inch, and a finger is carried into the bladder. If searching for a growth, find it by the finger. The usual rule has been to catch it in Thompson's forceps and twist it off. Such an operation is totally inefficient. Soft growths may be scraped away. Stop bleeding by digital pressure or by injections of hot water or adrenalin

chlorid (1 : 10,000). Median cystotomy does not allow anything like the freedom of access given by suprapubic cystotomy, and the latter operation is the best for tumor cases. The median operation may be used for drainage.

Fig. 895.—Senn's silver tube.

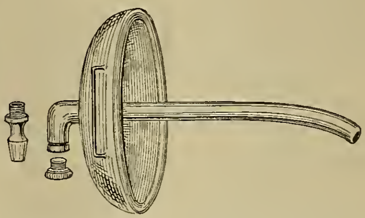

Fig. 896.—Stevenson's suprapubic drainage-tube.

Growths In the Female Bladder.—It was long the custom to dilate the urethra as in a case of stone, and scrape, twist, or pull the growth away or ligate it. This plan is inefficient, as by it the base of the tumor is not removed. It is usually best, if fulguration fails or will evidently be useless, to perform a suprapubic operation. If the growth is large or if there are multiple growths, always perform suprapubic cystotomy.

Diseases and Injuries of the Urethra, Penis, Testicle, Prostate, Seminal Vesicle, Spermatic Cord, and Tunica Vaginalis

Injuries of the penis and urethra may arise from traumatism to the perineum or the penis, from cuts and twists of the penis, from the popular "breaking" of a chordee, from tying string around the organ, from forcing rings

over it, from the passage of instruments, or from the impaction of calculi. Violence inflicted upon an erect penis may fracture the corpora cavernosa. The writer saw one man with a glass rod broken off in the canal, he having been in the habit of introducing it at the dictate of morbid sexual excitement. A patient in the Insane Department of the Philadelphia Hospital pushed a ring over his penis, which organ ulcerated into the urethra. These injuries are treated on general principles.

Perineal Bruises.—If the perineum is bruised without rupture of the urethra, the perineum and scrotum swell and become discolored; water is passed with difficulty because the extravasated mass of blood in the periurethral tissues compresses the canal more or less; the water is not bloody; and there is severe pain and much shock. Some authors include under rupture those cases in which laceration of the spongy tissue occurs, without involvement of the mucous membrane or of the fibrous coat, but they are properly contusions.

Treatment of Bruises and Wounds.—Place the patient in bed and establish reaction, and when reaction is complete employ opiates for the relief of pain. Apply an ice-bag to the perineum. If, notwithstanding these measures, swelling continues, introduce a silver catheter (No. 12 English), tie it in, and make pressure upon the perineum by a firmly applied T-bandage or by a crutch braced against the foot-board of the bed. Even when swelling is slight, retention of urine may occur from projection of a submucous blood-clot into the canal of the urethra. In some cases it may become necessary to incise the perineum and evacuate the blood-clot. After twenty-four hours have passed, if hemorrhage has ceased, substitute a hot-water bag for the ice-bag, and empty the bladder regularly by a soft catheter. Occasionally, though rarely, an abscess forms. *Punctured wounds of the urethra* require ordinary dressings. *Incised wounds of the urethra*, when longitudinal, are closed by suture. Healing is rapid and ill consequences are not to be feared. Stricture does not follow. When the wound is transverse, introduce a catheter, suture the wound over the instrument, and remove the catheter at the end of the third day. If a catheter cannot be introduced, employ sutures, but at the first evidence of extravasation open the wound, and if drainage is not free perform external perineal urethrotomy.

Rupture of the Urethra.—By this term is meant a lacerated or a contused wound of the urethra, destroying partially or entirely the integrity of the canal. A lacerated wound may be induced by fracture of the cavernous bodies during erection, the symptoms being severe hemorrhage, intense pain, retention of urine, and inability to pass an instrument; infiltration of urine occurs, and gangrene is a common result. The writer has seen 1 case of rupture of the penile urethra due to a man's slipping while shaving, the penis being caught in a partially open drawer, the drawer being shut by his body coming against it. Rupture, however, is almost invariably located in the perineum, and it arises when the urethra is suddenly and forcibly pressed against the arch of the pubes by a blow, by a kick, or by falling astride a beam or a fence-rail or on a wagon wheel. Retention of urine due to stricture may lead to extravasation of urine. The lesion of urethral rupture consists in some cases of laceration of the spongy tissue and the mucous membrane, a cavity being formed which communicates with the canal, and which fills with urine during micturition. In other cases not only the spongy tissue and the urethral mucous membrane are rent asunder, but the fibrous coat is also torn, the canal opening directly into the perineal tissues, among which a huge cavity forms, that fills with blood and later with urine and pus. The urethra may be torn entirely across, but in most cases a small portion at least of its circumference is uninjured. Rupture never occurs primarily and alone in the prostatic urethra. Some think it is extremely rare in the membranous urethra unless due to pelvic fracture. I believe that it occurs not unusually in the membran-

ous urethra. When we recall that this is the fixed portion of the tube we would expect rupture here rather than elsewhere. It is very unusual in the penile urethra. The seat of rupture in the great majority of cases is in the region of the bulb. Very rarely is the skin broken.

The **symptoms** of rupture of the fixed urethra are considerable pain, aggravated by motion, pressure, and attempts to pass water; decided shock; in some cases micturition is still possible, blood preceding and also discoloring the stream, for some blood usually runs into the bladder; retention of urine quickly arises; in a vast majority of the cases retention is absolute from the very first, and it is due to the interruption in the integrity of the canal and to the occlusion of the channel by blood-clots. Bleeding, which is usually free, lasts for several hours, some little blood generally appearing externally and much being retained in the perineum, inducing progressive swelling. The presence of a large swelling is regarded as evidence of urethral rupture. The blood which is effused in the perineum may extend under the fascia to the penis and scrotum. The swelling soon becomes reddish, purple, or even black, pressure upon it is apt to cause blood to run from the meatus, and it is augmented in volume when attempts are made to urinate. After a time, if the surgeon does not act, the urine fills the perineal cavity and widely infiltrates, and there ensue gangrene, sloughing, and sepsis, life being endangered or fistulæ being left as legacies. The course of the extravasated urine will often enable one to locate the seat of injury. In rupture of the membranous urethra, if uncomplicated, the urine remains between the two layers of the triangular ligament until a channel is opened for it by sloughing or by the knife. When extravasation occurs behind the posterior layer of the ligament the urine finds its way to the perineum in the neighborhood of the anus. When the rupture is in front of the anterior layer of the ligament the urine, directed by the deep layer of the superficial fascia, finds it way into the scrotum and up on the belly, but does not pass into the thighs (Fig. 899). A contusion is distinguished from a rupture by the facts that in the former the perineal swelling is not very extensive and does not enlarge on attempting micturition, while in the latter it is extensive and does enlarge on attempting to pass water. Furthermore, contusion does not cause urethral hemorrhage, while rupture does. A contusion sometimes, but not often, prevents the passage of a catheter; a rupture almost always, but not invariably, does so. The mortality from severe rupture with extravasation is about 14 per cent. (Kaufman).

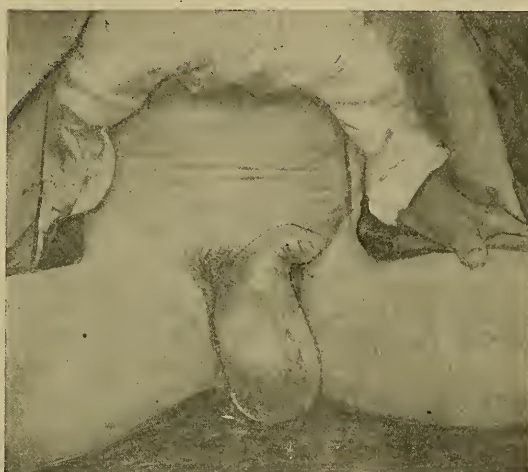

Fig. 899.—Rupture of the urethra and extravasation of urine.

Treatment.—In some very rare cases it is possible to suture the urethra, and this procedure should be carried out when possible. In order to suture, perform suprapubic cystotomy and also make a perineal section. Find the posterior end of the ruptured urethra in the perineum by passing a catheter from the bladder into the urethra. Suture by way of the perineum and with silk.

The sutures pass through all of the coats of the urethra. The roof of the canal is sutured first, then a steel sound is introduced from the meatus, and the urethra is sutured around the instrument. The sound is withdrawn and the bladder is drained by Cathcart's siphon as illustrated in Fig. 886 or by a double tube. In recent cases of ruptured urethra the usual treatment is as follows: Immediately perform median perineal section and turn out the clot; trim off lacerated edges; find the proximal end of the urethra, pass a catheter from the meatus into the bladder, and leave it *in situ* until healing has begun around it. If the catheter cannot be passed from the meatus, open the bladder above the pubes and find the proximal end of the torn urethra by retrograde catheterization. In retrograde catheterization we push an instrument from the bladder into the wound and use it to guide a catheter from the meatus into the bladder. When rupture occurs back of a stricture it is a good plan to excise the cicatricial tissue. In cases with extravasation make a median incision and numerous transverse cuts to secure drainage for areas of retained urine or pus. Then at once perform suprapubic cystotomy. Drain suprapubically and from the perineum for about two weeks, by which time sloughing tissue will have separated. Then find the posterior urethra by retrograde catheterization and do a perineal operation to repair the damaged urethra. (See Eugene Fuller, in "New York Med. Jour.," Nov. 23, 1901.) The wound is packed with iodoform gauze, and the bowels are tied up with opium for a few days. Some surgeons strongly disapprove of the custom of retaining the catheter, believing that the instrument does no real good, as urine is certain to get between the catheter and the walls of the urethra. They think it is quite enough to stuff the wound with gauze, the patient urinating through the wound for the first few days, after which time a catheter is used at regular intervals. Whatever method is employed, healing will require from six to eight weeks, and the patient must during the rest of his life, from time to time, introduce large-sized bougies.

Foreign Bodies in the Urethra.—These bodies may be calculi, bodies introduced by injury, as shot, bone, etc., bodies entering from a fistulous opening into the rectum, or bodies introduced from the meatus, as broken bits of catheters, straws, pins, etc.

The **symptoms** and **treatment** vary with the size and the nature of the body. Sometimes there are almost no symptoms; at other times there are found great pain, retention of urine, and hemorrhage. Examination is made by the urethroscope by feeling carefully with a finger in the rectum and by searching very gently with a sound, taking care not to push the body back. In some cases the body can be removed by aid of the urethroscope. Employ this plan if possible. If it is not possible, try the following plans: If the bladder is well filled with water when the body becomes impacted, inject a little oil into the meatus, close the lips with the fingers, and direct the patient to forcibly attempt urination, the surgeon opening the meatus when the urethra is widely distended, the foreign body being often forced out. If this maneuver fails, and the foreign body is impacted in the pendulous urethra, prevent its backward passage by at once tying a rubber tube around the penis. Try to squeeze the body out, and, if unsuccessful, endeavor to catch it with a wire loop, with a scoop, or with the long urethral forceps. If these methods fail, cut down upon the body and remove it, dividing any existing stricture. If it is lodged just back of the meatus, incision of the meatus will permit extraction. If a hairpin is in the canal, the points of the pin are almost always pointing to the meatus; to prevent them catching on attempted withdrawal, the penis must be squeezed to approximate the feet of the pin, and when they are adjacent a part of a silver catheter is slipped over to retain them in this position, when the pin can be extracted. If this fails, drag the penis against the belly, by rectal touch force the sharp ends of the pin out through the integument, cut one

end off, and then withdraw the other. An ordinary large-headed pin is forced out in the same way, and when the head is turned externally it is extracted by way of the meatus. If a hard or sharp foreign body is lodged in the prostatic urethra, do not catch it with an instrument and try to drag it forward. To do so will be apt to tear the membranous urethra. It is better to push it into the bladder and remove it later by cutting or, if it be a stone, by crushing (H. Hartmann, in "La Presse Méd.," July 24, 1901). If a lithotrite loaded with fragments be caught in the urethra, the surgeon must perform a perineal section, to enable him to clean and close the blades. After the blades have been closed the instrument may be easily withdrawn.

Urethrorrhea is not urethral inflammation, but is a condition of sensitiveness of the urethra and oversecretion of the glandular elements. It may be due to masturbation, sexual excess, and also, as Sturgis points out, to withdrawal during sexual intercourse, and to ungratified sexual passion. A drop or two of transparent mucus is found at the meatus in the morning, and a considerable amount may flow away while straining at stool or upon the diminution of an erection. This flow at stool is often called defecation spermatorrhea. This discharge stains, but does not stiffen linen (Sturgis). The discharge contains mucus, mucous corpuscles, epithelial cells, but no gonococci or pus organisms. The patient may be well in all other respects, but in many cases there are neurasthenic symptoms, sexual weakness, or even impotence. It is well to explain to the patient that the overaction of the muciparous glands is Nature's effort to facilitate the passage of the fluid of the orgasm and to alkalinize an acid urethra which would inhibit the activity of spermatozoids. Quacks fatten on these unfortunates. This condition may be readily distinguished from prostatorrhea by the absence of Böttcher's crystals (see page 1377) and from that very rare condition spermatorrhea by the absence of spermatozoids.

Treatment.—In an uncomplicated case improvement or cure will follow upon the abandonment of evil habits and the systematic passage of steel sounds. If complications arise, they must be treated.

Urethritis, or Inflammation of the Urethra.—Urethral inflammations can be divided into two classes: (1) *simple* or *non-specific*, in which infection is due alone to pyogenic cocci (particularly the Bacillus coli communis and the Staphylococcus pyogenes), and (2) *specific*, in which the gonococcus is present.

Non-venereal, non-specific, pyogenic, or simple urethritis may be due to several causes, such as traumatism; great acidity of the urine; chancre in the urethra; contact with menstrual fluid, leukorrheal discharge, the discharge from malignant disease of the uterus, ordinary pus, or acrid vaginal discharge; the passage of instruments; the administration of irritant diuretics; strong injections; worms in the rectum; a febrile malady; venereal excess and masturbation; the passage or impaction of foreign bodies, and papillomata of the urethra. A temporary and mild urethritis sometimes accompanies early syphilitic eruptions. Simple urethritis is less severe and prolonged than gonorrheal urethritis, though clinically in the early stage the physician cannot invariably distinguish between the two forms. The diplococci of gonorrhea are never found in the discharge of simple urethritis, although there may be numerous other diplococci. In medicolegal cases testimony is not admitted as to the presence or absence of diplococci, as judges do not admit that their presence proves or their absence disproves gonorrhea. In the non-specific inflammation pus is not always present, many cases stopping short of pus formation after a varying period of catarrh, but any catarrh may become purulent. A simple urethritis may be caused or may be prolonged for an indefinite period by the presence of large amounts of oxalate in the urine or the existence of the uric-acid diathesis (see Gouty Urethritis).

Treatment.—Seek for the cause and remove it. Correct any abnormal condition of the urine by means of suitable diet, drugs, and mode of life. Mild astringent injections are useful. It may be necessary to flush the urethra repeatedly with a solution of silver nitrate (1 : 8000).

Traumatic Urethritis.—The onset of pain in traumatic urethritis is coincident with the introduction of the foreign body. The discharge, which may be bloody, mucous, mucopurulent, or purulent, comes on within twenty-four hours.

Treatment.—If the inflammation is slight, prescribe diluent drinks, paregoric, a saline, or the following:

℞. Tinct. belladonnæ.. f℥ss;
Sodii bromid.. ʒiv;
Tinct. opii camphorat.. f℥j;
Syrupus zingib.. f℥ss;
Aquæ destil..q. s. ad. f℥vj.—M.
Sig.—A tablespoonful every six hours.

If the inflammation is severe, put the patient to bed, apply hot fomentations to the perineum, give diluent drinks, employ suppositories of opium and belladonna, and watch for fever and other complications.

Gouty Urethritis.—This condition first manifests itself in the posterior urethra, not in the anterior, as does clap. Its symptoms are great vesical irritability; pain on urination; discharge, usually scanty, associated with uric acid in the urine and perhaps joint symptoms of gout. The *treatment* comprises dieting and the usual remedies for gout. Purgatives are given freely, and full doses of colchicum, piperazin, urotropin, or the alkalis; hot baths, low diet, diluent drinks, and diaphoretics are indicated. A chronic discharge from the prostatic region is apt to linger; for this there is nothing better than the usual gouty remedies and saline waters with copaiba, cubebs, or sandalwood oil. In many cases it is necessary to flush the urethra once a day with a solution of silver nitrate (1 : 8000).

Eczematous Urethritis.—Berkley Hill states that this disease is very obstinate, is probably associated with gout, and is met with in adults of full habit or who are beer-drinkers and who have eczema of the surface of the body. He states also that the glans penis near the meatus is red and tender, and that the interior of the urethra is in the same condition. Pain is constant, and it is aggravated by micturition. The discharge is scanty. The *treatment* comprises injections of cold water or irrigation with iced water, and internally the administration of arsenic with the alkalis.

Tuberculous urethritis is due to a tuberculous ulcer, which is most apt to be seated near the vesical neck. There is a little pain on micturition, but there is intense pain at one spot on passing a bougie. The discharge is slight and at times bloody. The bladder is very irritable, and severe cystitis arises and persists. The *treatment* includes warmth, nutritious diet, and cod-liver oil, curettement, and local applications of iodoform through a urethroscope, and living as much as possible out of doors. The climate of southern California is peculiarly well suited to these cases. The bladder is washed out once a day with boric acid solution. Iodoform emulsion is injected daily. Tuberculin may prove of value. After a time the surgeon will probably be forced to drain by perineal or suprapubic cystotomy (see Tuberculous Cystitis, pages 1326 and 1327).

Pyogenic Chancroidal Urethritis.—This condition is sometimes seen in association with chancroid of the urinary meatus.

Pyogenic Urethritis of Urethral Chancre.—A urethritis may occur in this condition.

Pyogenic Syphilitic Urethritis.—A temporary and mild urethritis sometimes accompanies early syphilitic eruptions.

Examination of a Patient in Whom a Urethral Discharge Exists.—Learn accurately the history. Obtain some of the discharge and examine an unstained slide and a slide stained for gonococci. In some cases take cultures. Learn the amount of the twenty-four-hour urine and study a sample chemically and microscopically, being sure to determine the amount of urea. Learn if the discharge discolors or stiffens linen; if it is only found in the morning; if it simply glues the lips of the meatus together; if it is seen during the day; if it is noted particularly or only after sexual excitement or straining at stool. Inquire as to pain, frequency of micturition, passage of blood, nocturnal emissions, manner of urinating, etc. In many cases insert a finger in the rectum, feel the prostate and vesicles, massage them, and see if discharge appears at the meatus after stripping the penis. If discharge does appear, collect a specimen and examine it. In some cases it is necessary to pass a sound. Carefully cleanse the meatus, glans, prepuce, and urethra before passing a sound. Cleanse the meatus, glans, and prepuce with a 1 : 6000 solution of corrosive sublimate. Irrigate the urethra with boric acid solution and fill and clean urethra with emulsion of iodoform and glycerin (5 per cent.), and after using the instrument irrigate again with boric acid solution (Valentine's method). Examine the urine by the three-glass test.

The Three-glass Test (*Valentine's Plan*).—Take as many 3-oz. tubes as are required to receive all the urine from the bladder. The first tube contains the washings from the anterior urethra. The second and other tubes, additional material from the bladder. The last tube contains material expressed from the posterior urethra, prostate, and seminal vesicles. Examine the urine and the sediment in the first two glasses and in the last glass. Note particularly if *shreds* are present. The shreds of gonorrhea are white in color and of variable length, and float in the urine. They are composed of pus-corpuscles and of epithelial cells which have undergone fatty degeneration. Some of these shreds form in the ducts of Cowper's glands, some in the glands of Littré, some in the prostatic sinuses, some in the utricle, some in the folds around the verumontanum, and some from inflammatory patches along the entire length of the urethra. A 1 per cent. solution of methylene-blue injected into the anterior urethra will stain the urethral shreds, while those from the bladder will not be stained by it.

Gonorrhea (Clap; Specific Urethritis; Tripper; Venereal Catarrh).—Gonorrhea is an acute inflammation of the genital mucous membrane, nearly always of venereal origin, due to the deposition and multiplication of gonococci in the cells of the membrane and a mixed infection with the cocci of suppuration. The disease is inaugurated by gonococci. After a few days or more secondary pyogenic infection develops and complications may result from the gonococci or from the bacteria causing the mixed infection. The disease attacks with the greatest ease surfaces covered with squamous epithelium. The gonococci enter into and multiply in the superficial epithelial cells and pass between the deeper cells, where they lodge and multiply as the superficial cells are cast off. The pus from the urethra contains epithelial cells with gonococci on or inside of them, and also pus-cells with gonococci within them as a result of phagocytosis. Cultures are made with difficulty. Gonococci do not stain by Gram's method, but stain best with a weak, watery solution of an anilin dye. These bacteria are said not to be pathogenic to animals, although some observers deny this assertion. Gonorrhea is one of the most common and widely disseminated diseases. Probably one-half of all sterile women and many sterile men have been rendered so by this disease. It is responsible for not a few cases of abortion, for an enormous majority of female pelvic diseases, and it causes many cases of blindness by infection of children's eyes during delivery.

Gonorrhea in the Male.—In the male, clap begins within the meatus and fossa navicularis and extends backward throughout the length of the urethra. The mucous membrane swells and becomes hyperemic, and there is a discharge, first of mucus and serum, and then of pus. In severe cases the discharge is bloody (*black gonorrhea*) or green. For a week or more the inflammation increases, then becomes stationary for a time, and then declines, the discharge growing less profuse and thinner, a watery discharge lasting for a considerable time. An ordinary case of genuine gonorrhea lasts from six to ten weeks, and even a case limited purely to the anterior urethra will rarely be cured within four or five weeks. During the acute stage the entire penis swells and the corpus spongiosum becomes infiltrated with inflammatory exudate. An interesting fact is that gonorrhea may induce mild septicemia without demonstrable complications, the condition causing, according to Thayer ("Amer. Jour. Med. Sci.," Nov., 1905), a continued fever which, perhaps, lasts a number of weeks. In true gonorrheal septicemia the blood must contain gonococci (*gonococcemia*). In the case recorded by Thayer and in the one recorded by Blumer and Hayes, and in the one recorded by Stellwagen ("Therapeutic Gazette," April 16, 1910, page 248) cultures were obtained from the blood. Gonorrhea may produce grave septicemia with systemic complications. It tends particularly to attack serous membranes or other endothelial structures (joints, pericardium, endocardium, pleura, tendon-sheaths, intima of vessels, etc.). Among the complications are gonorrheal arthritis, myelitis, poliomyelitis, and multiple neuritis. There are 3 cases of gonorrheal myositis on record (Martin W. Ware, "Amer. Jour. Med. Sci.," July, 1901). Phlebitis may arise. Mild endocarditis may arise or severe endocarditis may occur, identical symptomatically with ulcerative endocarditis due to other bacteria. In 6 reported cases of endocarditis gonococci were obtained by cultures from the blood *intra vitam* (Thayer, Loc. cit.). Cerebral embolism may result. Cerebrospinal meningitis can occur (fluid obtained by lumbar puncture contains gonococci).

Gonorrheal rheumatism is discussed on page 636. Gonorrheal peritonitis is rare. Infection of the peritoneum through the blood is very rare. The majority of cases of gonorrheal peritonitis occur in women and are due to direct extension from the Fallopian tubes. Gonococci have not been found in the exudates of cases of pleuritis and pericarditis supposed to be of gonorrheal origin. A child may contract gonorrheal ophthalmia during delivery, and any person may develop it by getting gonococci into the eyes.

Symptoms of Acute Inflammatory Gonorrhea.—The period of incubation of gonorrhea is from a few hours to two weeks. The usual period is from three to five days, when symptoms of the *prodromal stage* or *stage of onset* begin. The patient notices on arising a drop of thin fluid which glues the lips of the meatus together, and he feels some heat and itching or tickling about the meatus or in the navicular fossa. There may be uneasiness or actual pain unconnected with urination, and there is sure to be scalding pain on urination. The meatus is red and swollen, has a glazed appearance, may be covered with a little mucopus, and the lips are glued together by the discharge. It may be possible to squeeze out a drop or two. Even so early the fluid contains gonococci. The urine appears clear, but on shaking some flakes are noted. They are epithelial cells. Within forty-eight hours the *first stage*, the *florid stage*, the *acute stage*, or the stage of increase, becomes established. The meatus is now red, swollen, and everted (*fish-mouth meatus*); the entire glans may be red and swollen; if the prepuce is long, it becomes swollen, reddened, and constricted, and in many cases very edematous; the lymphatics by the frenum and on the dorsum of the penis may be red, swollen, tender, and cord-like; micturition causes severe pain (*ardor urinæ*), which is due to distention of

the inflamed urethra and to stinging by the acid urine. Bumstead thus described the act of micturition in acute gonorrhea: "During the act the patient involuntarily relaxes the abdominal walls, holds his breath, and keeps the diaphragm elevated in order to diminish the pressure on the bladder and lessen the size and force of the stream" ("Venereal Diseases," by Robt. W. Taylor). Because of the narrowing of the canal the stream of urine becomes narrow, weak, twisted, forked, or is delivered in little bursts or drops. Retention may result from spasm of the muscles. When the acute or florid stage is fully developed, the entire urethra is inflamed from the meatus to the triangular ligament; there is constant uneasiness or actual pain in the penis and perineum, increased by walking and by sitting down suddenly or carelessly. Insomnia is common; *chordee* occurs, especially when the patient is warm in bed. By "chordee" we mean a condition of painful erection in which the penis is markedly bent. The rigid infiltration of the corpus spongiosum prevents it distending to accommodate itself to the enlarged corpora cavernosa, and in consequence the organ curves. There is frequent micturition, with tenesmus and a profuse creamy discharge, which is yellow, greenish, or even bloody. The discharge soils and stains the victim's linen and may crust upon the linen, the meatus, or the glans. The commonest complications of this stage are *balanitis* (inflammation of the mucous membrane of the glans penis), *balanoposthitis* (inflammation of the surface of the glans and the mucous membrane of the prepuce), *phimosis* (thickening and contraction of the foreskin, so that the glans cannot be uncovered), and *paraphimosis* (catching and fixation of the retracted prepuce behind the corona glandis, with such swelling of the glans and prepuce that it is impossible to bring the prepuce forward over the glans). This is a dangerous condition and it should be reduced at once. In the *second* or *stationary stage*, which lasts from the end of the first to the end of the second week, the acute symptoms of the first stage continue. The most common complications of this stage are *peri-urethral abscess* or *phlegmon* (infection of a urethral gland or of submucous structures), *folliculitis* (inflammation of the follicles of Littré), hemorrhage, retention of urine (which is rare), gonorrheal arthritis, lymphangitis, and diminutive bubo on the dorsum of the penis (*bubonulus*), solitary and painful bubo of the groin, which may suppurate, *Cowperitis* (inflammation of Cowper's glands), inflammation of the prostate or of the bladder, gonorrheal ophthalmia, and *chordee* (painful erection with downward bending of the penis). In the *third* or *subsiding stage* the symptoms gradually abate, the discharge becoming scantier and thinner, and finally drying up. This stage is of uncertain duration, and in it there may occur *epididymitis*, or inflammation of the epididymis. Among possible complications we may mention peri-urethral abscess or phlegmon, Cowperitis, cystitis, prostatitis, bubonulus, folliculitis, gonorrheal arthritis (see page 636), infective endocarditis, tenosynovitis, pyelitis, purulent ophthalmia, perichondritis, and peritonitis.

Examination for Gonococci.—Every urethral discharge should be examined for gonococci in order to make a positive diagnosis. This examination is made several times during the progress of the case, so as to determine when the organisms disappear. Many non-gonorrheal conditions are due to cocci strongly resembling gonococci. Free pus and numerous cocci usually mean gonorrhea. So do complications. The examination of the smear is not absolutely conclusive. Cultures are conclusive. If there is a free discharge, fluid for examination can be easily obtained. If the discharge is scanty or occasional, have the patient partially empty the bladder. Then the surgeon massages the prostate and urethra and smears fluid on the slide. Then the patient empties his bladder into two glasses. Each specimen is to be centrifuged and examined for pus (Keyes, "Amer. Jour. Med. Sci.," Jan., 1912).

The taking of a smear and its examination are easy. Place a drop of discharge upon a cover-glass, lay another cover-glass over this, and slide the glasses apart. Dry and fix the slides in the flame of an alcohol lamp. Bring the cover-glasses in contact with a saturated solution of methylene-blue in 5 per cent. carbolic acid water. The staining material is allowed to remain in contact with the slides for five or ten minutes, the glasses are washed with water, are then placed in a solution of 5 drops of acetic acid to 20 c.c. of water, and kept there "long enough to count one, two, three slowly," and are again washed with water. Examination with the microscope shows the gonococci stained blue.[1] In doubtful cases, especially when the microscope fails to show gonococci, make cultures. Cultures must be made in suspected gonorrhea in a child, from the fluid of an inflamed joint, from the discharge in gleet or purulent ophthalmia, and from the blood in obscure infections.

Subacute or **catarrhal gonorrhea** develops in men who have previously had gonorrhea, as a result of prolonged or repeated coition or of contact with menstrual fluid or leukorrheal discharge. There is profuse mucopurulent discharge, but very little pain on micturition, and seldom chordee or marked irritability of the bladder.

Irritative or Abortive Gonorrhea.—In this disease the symptoms, which are identical with those of beginning clap, do not increase, but disappear within ten days.

Chronic Urethral Discharges.—**Chronic urethral catarrh,** which may follow gonorrhea, is characterized by the occasional presence of a drop of clear, tenacious liquid. This discharge becomes more profuse as a result of sexual excitement or the abuse of alcohol.

The persistence of a small amount of milky discharge, because of localization of inflammation in one spot or the production of a granular patch or a superficial ulcer, characterizes *chronic gonorrhea.* There is some scalding on urination; erections produce aching pain; there are pain in the back and redness and swelling of the meatus. All the symptoms are intensified by sexual excitement, by coitus, by violent exercise, or by alcoholic excess.

Gleet.—If a chronic gonorrheal urethritis lasts over ten weeks, it is called gleet. In gleet the lips of the meatus are stuck together in the morning, and squeezing them discloses a drop of opalescent mucopurulent fluid (the *morning drop*). During the day the discharge is rarely found. The discharge is yellow or has a yellowish hue; it stains the linen distinctly, and contains pus shreds, epithelium, and at times gonococci. The urine is clear and contains pus, gonorrheal shreds, and comma-shaped hooks. The discharge is not obviously purulent, and contains amyloid corpuscles. There are frequency of micturition, pains in the back, and dribbling of urine, and a bougie may find a stricture of large caliber, or at least will discover that the urethra is rigid from inflammatory infiltration. A discharge may be maintained by *chronic prostatitis.* In this condition there are frequency of micturition; a sense of weight or dull pain in the perineum; diminished projectile force of the stream of urine; there is often a tendency to sexual excitement and premature emission. In *prostatorrhea* a milky discharge gathers in the urethra during sleep and flows during muscular effort or while the patient is at stool. The linen is stained but slightly and the lips of the meatus are not glued together on waking. There is a history of masturbation or sexual excess. The condition is not aggravated particularly by alcohol or sexual intercourse. In chronic anterior urethritis there is a discharge from the meatus or sticking together of the lips in the morning. In chronic posterior urethritis there is no discharge of pus from the meatus. If the three-glass test is made, it will be found that in a case of chronic anterior urethritis only the first portion will be cloudy and show shreds; if there is

[1] Schutz's method, as set forth by R. W. Taylor in his work upon "Venereal Diseases."

posterior urethritis of not very long standing, both portions will be a little clouded, the first containing clap shreds, the last hool-shaped shreds. In a very chronic case neither sample will be cloudy, but the first portion will contain shreds. In gleet the rigidity of the urethra causes the retention of small quantities of urine after each act of micturition, back of the thickened areas. This retained urine decomposes and adds to inflammation. Indulgence in alcohol, sexual excitement, or sexual intercourse aggravates the condition.

Treatment of Acute Gonorrhea.—*General Care.*—Wash the hands after touching the parts and dry them on an *individual towel*, which is not used upon the face. Wear a suspensory bandage. Avoid violent exercise, especially bicycle riding, and also wet. Moderate exercise is allowable. The patient must not only refrain from sexual intercourse, but must not permit himself to indulge in sexual excitement, and must not drink a drop of liquor, malt, vinous, or spiritous, unless he is a heavy or a regular drinker, in which case we should permit the moderate use of well diluted rye or Scotch whisky. Some men become actually ill without their regular daily stimulants and such men should have them in moderation. Some surgeons permit the moderate use of claret to all patients. At least twice a day wash the penis for five minutes in a cup of warm water containing 1 dram of salt. Passing the urine while the penis is immersed in warm fluid lessens ardor urinæ. Cut a small opening in a square piece of old linen, slip the linen over the glans, catch it back of the corona, and bring the ends forward with the prepuce. Never permit the cotton or linen to stick fast and plug up the lips of the meatus. If the lips tend to become sealed up, grease them with sterile vaselin. If the glans is completely naked, pin the foot of an old stocking upon the undershirt, put absorbent cotton in the toe, and place the penis within this bag. Never tie or fasten any material about the penis. The patient should drink freely of plain water or of water containing a little bicarbonate of sodium. He should obtain one bowel movement every day.

Diet and Instruction List (Dr. T. C. Stellwagen, Jr.).—*Meats.*—May have white meat of chicken, boiled fish, lamb.

Must not take beef, beef steak, veal, pork, liver, kidney, etc.; nor salt fish, meats, smoked, canned, or potted foods.

Vegetables.—May have rice, hominy, string beans, fresh peas, spinach, beans, baked potatoes (sweet and white), lentils, etc.

Must not take rhubarb, tomatoes, asparagus (Guitéras's rule. See Begg, in "Phila. Med. Jour.," June 7, 1902), lemons, oranges, limes, or preserved fruits.

Drinks.—Nothing but plain water and milk.

Must not take alcoholic beverages or carbonated drinks.

Must not take salt, spices, condiments, cheese or pickles.

Desserts.—Only of the simplest kind, made from milk and eggs, and take them only sparingly.

General Rules.—Put on a suspensory bandage and wear it in conjunction with a piece of linen or a bag to catch discharges.

Wash the hands after handling the parts, and keep the fingers away from the eyes.

Keep the linen from contaminating the family wash.

Wash the organ frequently in warm salt water (1 teaspoonful of table salt to 1 glass of water).

When urination causes burning, immerse the organ in a basin of warm water and allow the urine to flow.

Keep the body warm and free from chilling.

Should not go about on rainy or snowy days without ample protection.

Should go to bed early.

Must not take cold baths. May take warm ones.

Should not eat between meals—it is unwise to overload the stomach.

Should drink freely of plain water or milk.

Should urinate when the desire comes.

Should keep away from females socially and sexually—and any other exciting influences, such as erotic sights, thoughts, and literature.

Must keep bowels loose.

A smoker should decrease the consumption of tobacco.

Never put pieces of cotton over the end of organ, as cotton so used prevents the free drainage of discharge. Should the lips of the opening seal together, wash clean in warm salt water and grease with vaselin.

A tea or coffee drinker may have a small amount once daily, but it will be better not to partake of either.

Should the patient be using an injection and find that the desire for urination becomes frequent at night, he must stop the injection and consult his physician.

The injection is never to be forced into the organ; it is to be introduced gently, and the bladder is to be empty when an injection is given.

Abortive treatment may be tried if the case is seen early. The use of strong solutions of powerful germicides has been abandoned because of the great pain they produce and the inevitable subsequent crippling of the urethra.

Abortive treatment is applicable only to specially selected cases and even then usually fails. It should never be used after the gonococci have invaded the submucosa, but only during the prodromal stage, when it is hoped that the germs are upon and not in the mucous membrane. This stage usually lasts but a few hours, usually not over forty-eight. The patient generally presents himself after this period has passed. When the symptoms as described in the prodromal period prevail, the abortive treatment may be tried, after explaining to the patient that it will cause some pain and discomfort and in the end may fail or even aggravate the inflammation.

Germicides may be used and with some chance of killing the infection, for as yet the organisms are growing upon the superficial strata of epithelium much as a sod of grass upon soil. When the deeper structures have been invaded it is folly to attempt to abort the disease.

The method advocated by White and Martin and which has proved successful in Prof. Hiram Loux's clinic in a limited number of selected cases is as follows: After urination 4 drops of a 4 per cent. solution of eucain are injected into the urethra; after which 2 drams of $\frac{1}{4}$ per cent. solution of protargol are instilled and retained for three minutes. The injections are repeated every two hours while awake.

Each time the bottle is half emptied it is replenished with sterile water to its full capacity, until the end of the third day. If successful, recovery is accomplished in about seven days. Should a mucoid discharge persist an antiseptic astringent injection is employed to complete the cure. During the treatment the patient must be kept at rest. The diet should be bland and light and the usual balsamic remedies are administered. If the symptoms become hyperacute, stop the treatment at once and give a sedative.

Another abortive method is the use of hot retro-injections of corrosive sublimate solution (1 : 20,000), 2 pints being run through the urethra once a day. If in seventy-two hours the symptoms are not greatly improved, abortive treatment should be abandoned. Recent studies render it almost certain that there is no real abortive treatment. Abortive treatment, to be efficient, would have to be carried out before the gonococci penetrated the epithelial cells; in other words, would need to be instituted before the distinct symptoms of the disease appear. Janet says that we must alter our conception as to what

constitutes abortive treatment, and he doubts if a case of true gonorrhea was ever really aborted.[1] The method of irrigation with solutions of permanganate of potassium is really a prophylactic treatment. Janet applies his treatment as evidences of trouble present themselves, and before acute symptoms appear, and claims that in most persons the disease can be arrested in from eight to twelve days. The same plan of treatment is useful in a well-developed case.

Irrigation in Gonorrhea.—Irrigation can be used in an incipient or in a well-developed case. Janet's method is as follows: An irrigator is filled with a warm solution of permanganate of potassium (1 : 4000). The patient after emptying his bladder is seated upon a chair and his sacrum rests upon the extreme front edge of the chair (Valentine's position). The reservoir is joined to a glass nozzle by a rubber tube. The nozzle is introduced into the meatus, and the fluid is permitted to run gradually at first, with full force later. In anterior trouble the fluid is allowed to run out of the meatus by the side of the nozzle. The anterior urethra is always irrigated first, the reservoir being 2 feet above the chair.

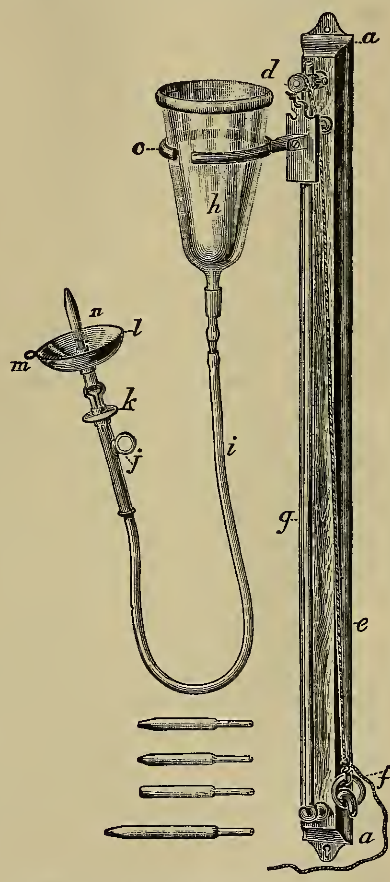

Fig. 900.—Valentine's urethral and intravesical irrigator: *a*, Board with attachments to be screwed to wall; *c*, open collar; *d*, pulley; *e*, cord; *f*, ring to suspend percolator; *g*, brass rod; *h*, percolator; *i*, rubber tube; *j*, ring for fourth finger; *k*, flange to graduate pressure; *l*, shield; *m*, ring to suspend shield; *n*, nozzle attached.

In posterior urethritis, after the anterior urethra has been irrigated, the reservoir is raised from 6 to 7 feet above the bed, the meatus is held tight about the nozzle, and the fluid overcomes the force of the compressor muscles of the urethra and the bladder sphincter and enters the bladder. If the muscles do not quickly relax, continue the hydrostatic pressure for several minutes, when relaxation will usually occur; but if it does not do so, tell the patient to breathe slowly and deeply, and to make efforts at urination (Valentine's plan). When the bladder is full the tube is withdrawn and the patient micturates. This procedure is practised once or twice a day for five or six days, or even longer, and the strength of the solution is gradually increased up to 1 : 1000. It has been claimed that after one or two weeks of this treatment gonococci permanently disappear in the majority of cases. Figure 900 shows the ingenious and very useful irrigator devised by Ferd. C. Valentine, of New York. Valentine[2] has constructed the table on page 1352, which is of use to a practitioner who wishes to employ irrigations with permanganate of potassium in the treatment of acute gonorrhea. I followed the method set forth in the table in a great number of cases, and regarded it an extremely useful systematic plan.

For full directions regarding this method see Valentine's book, "The Irrigation Treatment of Gonorrhea." If a stricture exists, it is not advisable to employ this treatment. Excellent results can be obtained by irrigations with fluid containing silver nitrate (1 : 12,000 to 1 : 8000).

When a patient is treated by irrigation, after the entire subsidence of acute symptoms, a thin, colorless discharge may persist. This can be cured by the use of astringents. Two or three times a day an astringent is injected by means of a $\frac{1}{2}$-ounce syringe. Dalton's formula is very useful: Zinc oxid and lead acetate, of each, $\frac{1}{2}$ to 3 gr.; tincture of catechu, from 10 to 30 min.; glycerin, from $\frac{1}{2}$ to 1 dram; and water to make 1 oz. Ultzmann's formula is: Zinc sulphate, 16 gr.; pulverized alum, 8 to 12 gr.; carbolic acid, 3 gr.; and water to make 4 oz.

Many writers oppose the irrigation treatment, claiming that it increases the liability to complications, especially prostatic inflammation, and enhances the danger of recurrence. I believe in the method. I do not think it shortens materially the duration of the disease, but do believe that it mitigates its intensity, makes the patient much more comfortable, and quickly causes the discharge to become mucopurulent. That it increases complications and the danger of reinfection is very doubtful. Much of the trouble which has followed its use has been due to raising the reservoir to too great a height.

Irritative gonorrhea will subside in a few days. The above directions should be followed, and the anterior urethra should be washed out several times daily with diluted peroxid of hydrogen, or irrigated once a day with a hot solution of permanganate of potassium (1 : 4000). In *catarrhal gonorrhea* at once order injections (1 gr. to the ounce of sulphate of zinc; or zinci sulphas, 8 gr., plumbi acetas, 15 gr., water 8 oz.; or 5 gr. of sulphocarbolate of zinc to 1 oz. of water; or White's prescription of 1 dram each of acetate of zinc and tannic acid, 8 drams of boric acid, 6 oz. of liq. hydrogen peroxid). For injecting use a blunt-pointed hard-rubber syringe of a capacity of 3 or 4 drams. Let the patient urinate and then sit on a chair, his buttocks hanging over the edge; throw a syringeful of the solution into the urethra and let it run out at once, and throw in another syringeful and hold it in from three to five minutes.

In *ordinary acute gonorrhea* we follow an old rule when we order balsams. The common custom is to give two capsules three times a day, each capsule

containing 5 gr. of salol, 5 gr. of oleoresin of cubebs, 10 gr. of balsam of copaiba, and 1 gr. of pepsin. Clinical observation indicates that the balsams are of distinct value in gonorrhea. When used early, the discharge tends to become mucopurulent and the acute symptoms usually soon begin to subside (S. Behrmann, in "Dermatologisches Centralblatt," Berlin, Nov. and Dec., 1901). Many practitioners will not use balsams until the third week. Bacteriological studies indicate that copaiba, when eliminated in the urine, has a certain amount of power in inhibiting the growth of gonococci, but that cubebs and oil of sandal have not such power. Yet oil of sandal is more useful than copaiba as a remedy. Salol is distinctly germicidal, hence it is given with the balsams. In a case treated by balsams an astringent injection is usually employed. The injection is used two or three times a day, immediately after micturition. As the inflammation subsides the strength of the injection should be gradually increased. A good plan is to order an 8-oz. bottle and 8 1-gr. powders of sulphate of zinc. Direct the patient to fill the bottle with water, in which one powder is dissolved; when this is used dissolve 2 powders in a bottleful of water, and so progressively increase the strength. When the discharge ceases stop the injections gradually. Whenever a syringeful is taken from the bottle a syringeful of water is put into the bottle, and thus pure water is soon obtained, at which point injection is discontinued. If a simple astringent injection causes much pain, use a sedative injection—2 drams of boric acid, 8 gr. of aqueous extract of opium, and 8 oz. of liquor plumbi subacetatis dilutis. I have had about as much success with the above simple method as with the most complicated of plans. Complication and complexity are not criterions of usefulness.

Argonin, which is a combination of albumin, silver, and an alkali, is highly recommended by some authors as a local remedy for gonorrhea (Schäffer, Guthiel). A solution of this material is non-irritant, the silver is not precipitated by chlorids, and the agent destroys gonococci. It is used by injection or irrigation. If used by irrigation, employ a 1 : 500 solution twice a day. If used as an injection, employ a 1 : 200 solution six or eight times a day. When the discharge is found free from gonococci and remains free for three days, stop the argonin and use an astringent injection.

Protargol, metallic silver combined with a protein, is a yellow powder soluble in water, the solution not being acted on by light. It is a non-irritant germicide. Neisser, after demonstrating the presence of the gonococcus, administers protargol by injection, the first injections being of a strength of 0.25 per cent., the strength being gradually increased to 0.5 per cent., and finally to 1 per cent. In the beginning he orders three injections a day, each injection being retained from fifteen to thirty minutes; after several days, when the symptoms improve, he gives only one or two injections a day, and these are continued for ten days after gonococci disappear from the discharge. After protargol is abandoned an astringent injection should be used for a time. Some surgeons use a 1 : 1000 solution of protargol, and irrigate the anterior urethra and flush the bladder twice a day. A silver salt used by many is argyrol, or silver vitellin. The injection used at first may be of a strength of 2 per cent. The drug should be retained in the urethra four or five minutes, and three or four injections should be given each day. The strength of the injection can be gradually increased to 5 per cent. or even more. I have not been impressed with the value of this preparation except in the earliest stages of gonorrhea. Picric acid has been highly commended as an injection. The strength of solution is 1 : 200, and it is to be retained in the urethra three or four minutes (de Brun's method).

Methylene-blue internally is occasionally of service in gonorrhea. A capsule containing 1 or 2 gr. of the drug is given three times a day. It makes the

urine greenish blue and occasionally induces strangury. Urotropin renders the urine sterile. Salicylate of sodium may be of value late in the case.

In his clinic in Jefferson Hospital my colleague, the late Prof. Horwitz, introduced the following plan of treatment: A capsule containing balsam of copaiba, salol, oil of sandal, and methylene-blue is given half an hour after each meal:

℞. Methylene-blue.. gr. xxx;
Balsami copaibæ }
Olei santali } ....āā f℥iss.—M.
Pone in capsulas No. xxx.
Sig.—One after each meal.

The patient begins at once to take, by hand injection, a 10 per cent. solution of argyrol. He takes it three times a day,

At each daytime injection the fluid is retained in the canal for five minutes. At the bedtime injection the fluid is retained for fifteen minutes. At first only about 1 dram is injected at a time, but as the urethra becomes accustomed to fluid distention the amount is gradually increased, until finally 4 drams may be given.

When the stage of decline begins (toward the end of the second week) a combined astringent and antiseptic treatment is used.

The capsules of methylene-blue, copaiba; and sandal, and the injections of argyrol are discontinued. A capsule containing oleoresin of cubebs, oil of sandal, and balsam of copaiba is given before each meal, and a capsule of urotropin is given after each meal. An injection of protargol ($\frac{1}{4}$ of 1 per cent.) is given three times a day. This remedy is germicidal and also astringent. The strength is gradually increased until a 1 per cent. solution is used. By the end of the fourth week the patient has reached the terminal stage. Now capsules of sandal and salol are substituted for the cubebs, sandal and copaiba and an astringent injection is ordered. The following injection, recommended by J. Wm. White, is very satisfactory:

℞. Hydrarg. chlor. corros.................................. gr. $\frac{1}{8}$;
Zinci sulphocarbolas.................................. ℥ss;
Acidi boraci.................................. ℥ij;
Acidi carbolici.................................. ♏xv;
Boroglycerid (25 per cent.).................................. f℥ij;
Aquæ destil..................................q. s. ad. f℥vj.—M.
Sig.—Inject. Dilute if it causes much pain.

When the mucoid condition predominates in the discharge the following is useful:

℞. Zinci sulph.................................. gr. xv;
Plumbi acetati.................................. gr. xxx;
Glycerol tannin }
Hydrastin (Lloyd's) } ....āā f℥iv;
Mucil. acaciæ.................................. f℥iv;
Aquæ destil..................................q. s. ad. f℥vj.—M.
Sig.—As injection.

The formula of the "injection Brue" is as follows:

℞. Plumbi acetat.................................. gr. xxx;
Zinci sulphat.................................. gr. xvj;
Ext. krameriæ fl.................................. f℥iv;
Tinct. opii.................................. f℥iij;
Aquæ destil..................................q. s. ad. f℥vj.—M.
Sig.—As injection.

When all symptoms of clap have disappeared, any injection in use is gradually diluted. Whenever a syringeful of the fluid is taken from the bottle, a syringeful of water is put in. When the fluid becomes pure water the injection is discontinued. Balsams are stopped by gradual diminution in the number of daily doses. For three weeks after the entire disappearance of all symptoms alcohol is forbidden and sexual indulgence is prohibited. Should a relapse occur the patient is at once placed upon treatment as for the acute stage, and when the stage of decline again ensues he is placed again on antiseptics and astringents. Relapses are caused by a localized lesion or lesions in the anterior or posterior urethra, hence as soon as all acute symptoms subside an endoscopic examination is to be made and proper treatment is to be applied to any localized lesion. If during the treatment of gonorrhea a complication develops, local treatment of the urethra is at once discontinued and constitutional treatment suited to the new condition is prescribed.

If the onset of gonorrhea is marked by violent inflammatory symptoms (chordee, hemorrhage, severe pain, swelling, profuse purulent discharge), local treatment of the urethra is contra-indicated.

If the invasion is hyperacute, no local treatment of the urethra is permissible until the disease assumes the character of ordinary gonorrhea.

Not unusually gonorrhea passes into a low grade of anteroposterior urethritis that proves most rebellious to treatment. This condition is especially common when too stimulating treatment has been used. A mild astringent injection should be used three times a day. Every second or third day an injection of nitrate of silver (1 : 4000) should be given. If the silver salt sets up an acute inflammation the treatment used in the acute stage of gonorrhea is given until the symptoms abate.

A valuable plan in rebellious anteroposterior urethritis is daily irrigation of the anterior urethra with a warm solution of permanganate of potassium (1 : 6000), followed by the passage of a soft catheter and the filling of the bladder with a like solution. The patient empties his bladder after the catheter is withdrawn and thus flushes the entire urethra with the permanganate. The strength of the solution is gradually increased up to 1 : 2000.

Weiss uses corrosive sublimate (1 : 20,000) in the manner just described. It is particularly valuable in cases of bacterial contamination, the gonococci having disappeared.

Treatment of Complications.—*Ardor urinæ* is relieved by urinating while the penis is immersed in hot water and by administering alkaline diuretics. *Chordee* requires a bowel movement in the evening, and sleeping in a cool room, under light covers, and on a hard mattress; bromid of potassium is given several times daily, and a considerable dose is given at night; it may be necessary to use suppositories of opium and camphor or to give hyoscin. *Balanitis* requires frequent washing of the head of the penis and prepuce in warm water, drying with cotton, and dusting with borated talc, stearate of zinc, or boric acid and subnitrate of bismuth (1 : 6). *Balanoposthitis* requires soaking in hot water, and injections of black wash under the prepuce until edema of the foreskin subsides, and then cleanliness and the application of a drying powder. *Phimosis* requires soaking the penis in hot water, and injections of hot water beneath the foreskin, followed by black wash. If this fails, circumcision must be performed. If *paraphimosis* occurs, grasp the head of the penis with the left hand, squeeze the blood out, and try to push the head back, while with the right hand the penis is pulled upon as if the surgeon intended to lift the individual by the organ. If this fails, cut the collar on the dorsum with scissors; or, what is better, for it gives free exposure, incise each side of the prepuce between the middle of the dorsum and the frenum. *Bubo* requires the application of iodin, ichthyol, or blue oint-

ment, the use of a spica bandage, and rest. If a bubo suppurates, it must be opened or aspirated. *Acute posterior urethritis* is treated by rest, and if the symptoms are severe, by rest in bed. If the balsams do not irritate, they are given; if they do, they are withdrawn. Urotropin or salol is given and the patient is placed upon a milk-diet with orders to drink largely of flaxseed tea. Alkaline fluids do harm by favoring ammoniacal decomposition of the urine. Injections and irrigations are abandoned. Pain and vesical spasm are controlled by suppositories of opium and belladonna. If retention of urine occurs, have the patient urinate while in a hot bath; if this fails, use a soft catheter. *Acute vesiculitis* is treated as is acute prostatitis. Chronic vesiculitis is considered on page 1375. *Pyelitis* is treated by rest in bed, hot baths, wet cupping of the loin, milk-diet, diuretics, the taking of a large quantity of bland liquid, and the administration of salol or urotropin, and in some cases lavage of the kidney pelvis through a ureteral catheter with one of the silver preparations (1 : 15,000 of nitrate of silver). *Folliculitis* is treated by rest and the application of a hot-water bag to the perineum (if that be the part involved). If pus forms, evacuate by incision. Later the follicle may be dissected out or destroyed by cauterization. If the follicle opens into the urethra it may be cauterized through an endoscope. *Peri-urethritis* is treated by rest and hot applications. If pus forms, an incision must be made. If the abscess is permitted to break into the urethra, rest and hot fomentations may be used, but at the first sign of urinary extravasation make an external incision. *Cowperitis* is treated in the same way as peri-urethritis. Gonorrheal rheumatism is considered on page 636. *Acute prostatitis* and *cystitis* require confinement to bed, a milk-diet, the use of diuretics, hot applications to the perineum and hypogastrium (bags of hot sand), suppositories of opium and belladonna or of ichthyol, leeching the perineum, the discontinuance of balsams and injections, and the administration of urotropin or salol. Heat can be applied by means of a stream of warm water which circulates through a metal instrument introduced in the rectum. *Abscess of the prostate* requires instant incision. In *retention of urine* the patient should try to pass the urine while in a hot bath; if this fails, a soft catheter is used. After relieving the bladder put the patient to bed and apply hot sand-bags as for acute prostatitis. *Chronic prostatitis* requires cold hip-baths, cold-water enemata, deep urethral injections, massage of the prostate, plain diet, avoidance of alcohol and overexertion, counterirritation of the perineum, and the relief of stricture or phimosis. Great benefit is occasionally derived from passing a soft bougie covered with blue ointment or with a 1 per cent. ointment of silver nitrate. If there are pus pockets, gonorrheal phylacogen may perhaps be of service. If *epididymitis* arises, put the patient to bed, abandon injections, shave the hair from the groin, leech over the cord, elevate the testicles, and early in the case apply an ice-bag. Give a cathartic, a fever mixture, and suitable doses of bromid of potassium and morphin. The local application twice a day of 20 drops of guaiacol in 1 dram of cosmolin or olive oil gives relief. When swelling lingers, after tenderness subsides strap the testicle with adhesive plaster. A lingering case is benefited by the internal use of iodid of potassium and the local application of ichthyol. In *gonorrheal ophthalmia* secure a watch-crystal over the unaffected eye, put the patient in a darkened room, rub the infected conjunctival sac with cotton soaked in a 2 per cent. solution of silver nitrate, wash out the affected eye repeatedly with hot boric acid solution, keep the pupil dilated with atropin, leech the temple, and give purgatives. Always send for an ophthalmologist.

When is Gonorrhea Cured?—It is said that Ricord declared: "We know when clap begins, but God alone knows when it ends." When actual discharge ceases a patient considers himself cured, and yet he may have residues of

infection which are liable at any time to awaken into activity and produce anew an acute condition. Gonococci are frequently retained in the urethral glands and follicles or in areas surrounded by indurated mucous membrane. Gonococci may linger in these haunts for many months, some say for years. Keyes, however, maintains that they never persist in the male urethra over three years and that in 90 per cent. of cases, with or without treatment, they disappear within one year (Edward L. Keyes, Jr., in "Amer. Jour. Med. Sci.," Jan., 1912). It is customary to consider a man well when, after he has been without treatment for one week, shreds and pus disappear from the urine, when an examination of expressed mucus on three successive days fails to find gonococci, and when there has been no discharge for ten days. Furthermore, we must be sure that the prostate, Cowper's glands, and the seminal vesicles are free from disease. Never declare a man well under three months from the start of the disease unless gonococci are positively absent from the urine and the expressed discharge.

If a patient has "no morning drop," has been apparently well for three or four months, has no pus in the morning urine or in the expressed secretion of the urethra, prostate, and seminal vesicles, we can, without making cultures, affirm that he is well (Keyes, Ibid.).

Keyes also maintains that a man with a "pearly morning drop" who passes a urine containing pus-shreds, but who has no free pus in expressed secretions, is probably free from gonorrhea.

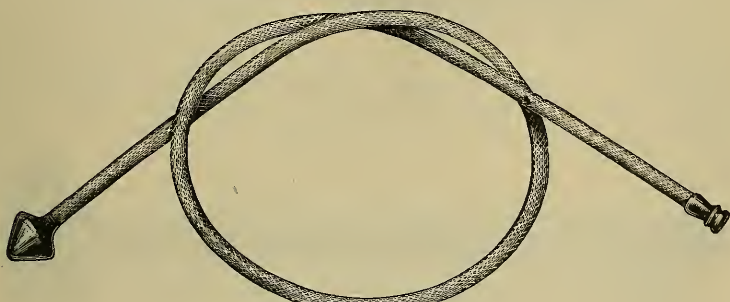

Fig. 901.—Bougie-à-boule.

Treatment of Chronic Gonorrhea and of Chronic Urethritis Following Gonorrhea.—The first thing to do is to determine the *cause* of the prolongation of the discharge. Valentine's list of causes should be borne in mind ("Med. Record," June 29, 1901). They are as follows: (1) Lack of treatment; (2) misdirected treatment; (3) insufficient treatment; (4) overtreatment; (5) infraction of dietetic or hygienic regulations; (6) constitutional disturbances; (7) congenital or acquired deformities and complications; (8) involvement of the urethral adnexa; (9) marital reinfection. In a case in which a discharge persists or recurs the symptoms and general condition must be closely studied, the discharge must be examined microscopically, the condition of the urine must be determined, and the urethra must be explored.

Exploration of the urethra is inaugurated by inspection and external palpation. Palpation detects induration, peri-urethritis, follicular abscess or inflammation, Cowperitis, etc. The prostate and seminal vesicles are examined by a finger in the rectum. The interior of the urethra is explored by a soft bougie-à-boule (Fig. 901). On withdrawing this instrument the shoulder catches in any contracture. It is to be borne in mind that a large steel sound can often be introduced with ease when the bougie-à-boule makes evident that a contracture exists. The emergence of the instrument is arrested

by a patch of thickening, a granular area, a zone of epithelial proliferation, a papilloma, or a stricture. In fact, anything which lessens the urethral caliber interferes with the withdrawal of the bougie-à-boule. It does not do to conclude that stricture exists simply because some lessening of caliber is appreciated. The bougie-à-boule finds its chief use in exploring the anterior urethra. If introduced into the deep urethra its emergence will be normally checked as its shoulder comes against the posterior layer of the triangular ligament.

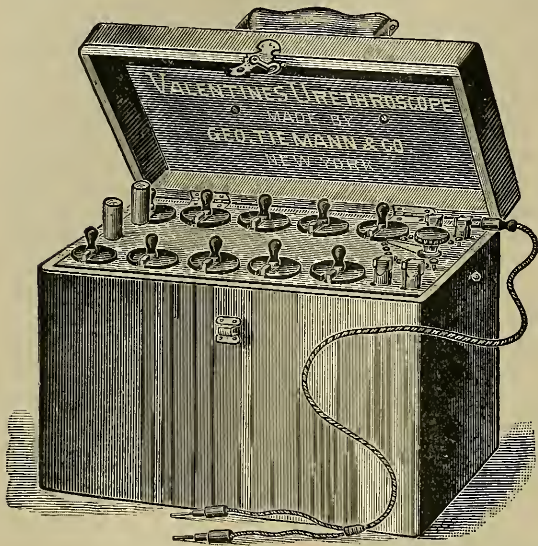

Fig. 902.—Valentine's urethroscope.

In most cases the diagnosis is only certainly determined by the use of the urethroscope. This instrument has been perfected of recent years and is now an absolutely essential part of our armamentarium. I have long used Valentine's instruments (Figs. 902–905). Marks's air-dilating urethroscopes (Figs. 906, 907)

Fig. 903.—Valentine's urethroscopic tube.

are highly satisfactory. The anterior and posterior urethra can be thoroughly examined and with the utmost ease. Before inserting a urethro-

Fig. 904.—Valentine's obturator.

scopic tube place the patient recumbent and cleanse the foreskin, glans, and anterior urethra as directed in the section on Cystoscopy. Insert a tube which

Fig. 905.—Valentine's light carrier.

readily passes the meatus, first cleansing the tube and obturator by burning alcohol upon them. Carry the tube to the anterior layer of the triangular liga-

ment. Withdraw the obturator and insert the light. Turn on the light, mop the urethra with bits of cotton wrapped on a stick, and slowly withdraw the tube, examining the urethra as its walls fall together back of the retracting tube. After withdrawal of the tube irrigate the anterior urethra. To examine

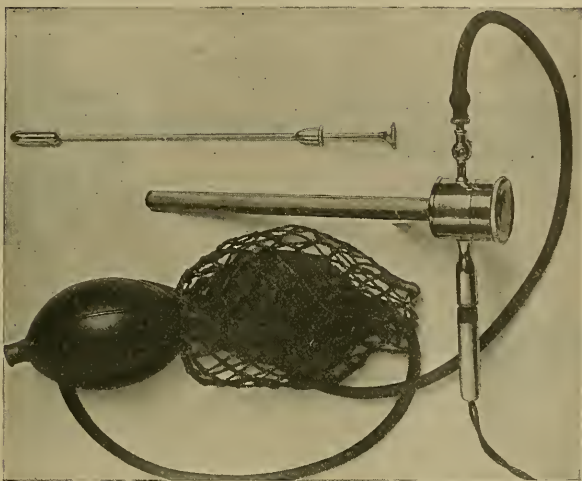

Fig. 906.—Marks's air-dilating urethroscope for examination of the anterior urethra.

the deep urethra carry the instrument through the prostatic urethra. After the examination give an intravesical irrigation.

When the cause of a discharge is once determined, rational treatment can be instituted, and to determine the cause the electric urethroscope is indispensable. An erosion of the mucous membrane or a granular patch requires

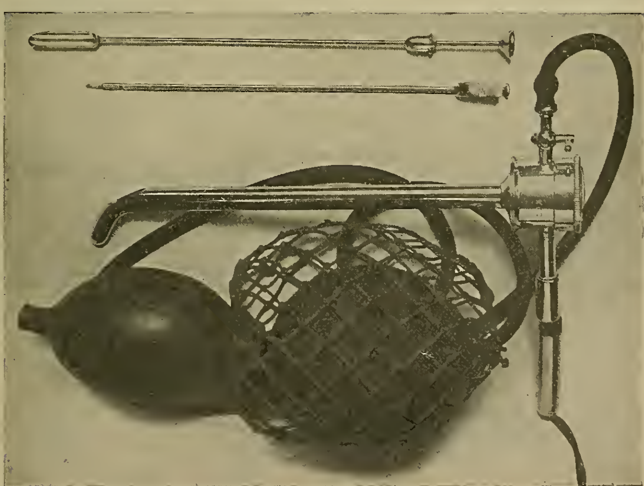

Fig. 907.—Marks's air-dilating urethroscope for examination of the posterior urethra.

touching from time to time with a solution of silver nitrate (1 or 2 per cent. or even much stronger). These applications are made through the tube of the urethroscope. A stricture or an infiltration is treated by gradual dilatation. This combines pressure and massage. If the caliber of the urethra is less than

No. 21 of the French scale, conical steel sounds are used twice a week. If there is much hyperesthesia they are retained but a brief time; but as hyperesthesia diminishes the period of retention is lengthened, until an instrument can be kept in place without causing severe suffering for ten or fifteen minutes. It is not desirable to use cocain. Its use is not free from danger and, further, it

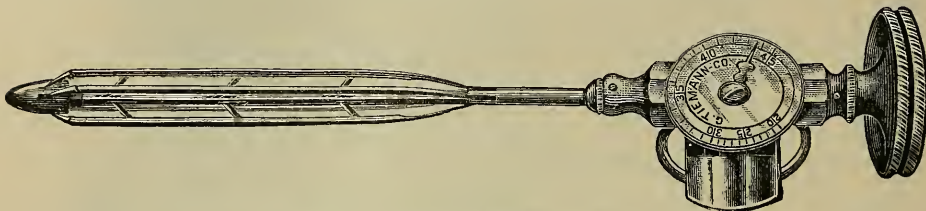

Fig. 908.—Kollmann's anterior dilator.

Fig. 911.—Oberlander's anteroposterior dilator.

obtunds the sensibility so that undue violence may be used, and it increases postoperative inflammation. Before and after using an instrument the urethra must be cleansed by irrigation with salt solution or permanganate of potassium.

When the urethra becomes tolerant to instrumentation, a special dilator is employed to act particularly on the area of disease. If in the beginning of treatment the caliber of the urethra is equal to or greater than No. 21 of the

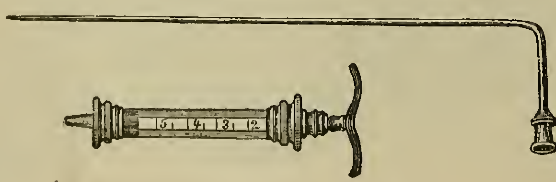

Fig. 912.—Kollmann's gland syringe.

French scale, it is rarely necessary to precede the dilator by the use of conical sounds. Figs. 908–911 show various dilators. A dilator unless of a very modern type should be inserted in a sterile rubber cover before being used, otherwise it will cut, tear, or pinch the urethra when closed and withdrawn. Kollmann's dilator (new style) will not injure the mucous membrane and can

be used without a cover (Fig. 908). A dilator should be lubricated with lubrichondrin, synol soap, or liquid cosmolin. If a two-bladed dilator is used at first, a four-bladed dilator must be subsequently employed.

A dilator is cleansed by scrubbing its blades with soap and water, sticking them in alcohol, withdrawing, and burning the alcohol retained in the instrument.

The following rules for dilatation are of the first importance (Ferd. C. Valentine, in "Med. Record," June 29, 1901):

1. The first dilatation must stop at that point at which the first resistance to further dilatation is felt by the operator's fingers turning the screw that separates the blades.

2. Dilatations, if done by a novice, must in the beginning of treatment be repeated no oftener than every three or four days.

3. Each dilatation, in point of time, must reach no greater duration than two minutes over that of the preceding session.

4. No dilatation must exceed one-half number Charière above the number attained at the next prior séance, regardless of any lack of resistance that may be present.

As a rule, glandular and follicular infiltrations are cured by the use of the dilator. If they are not, they must be treated through the tube of the urethroscope. The interior of a follicle may be cauterized by a heated electric wire, subjected to electrolysis, fulgurated by the Oudin current, or touched with a 3 per cent. solution of silver nitrate. A thickened crypt, gland follicle, or an area of induration may be slit by a knife. A polyp can be removed by a snare, the cautery, or special forceps. In a chronic inflammation of the urethra, in which the inflammation is superficial and in which the glands are not involved, irrigations, urethral and intravesical, constitute the best treatment. (See Valentine's treatise on "The Irrigation Treatment of Gonorrhea, its Local Complications and Sequels.")

In any lingering case of gonorrhea examine the urine, and direct suitable treatment for oxaluria, lithemia, or phosphaturia, if any one of these conditions exists. Such morbid states of the urine are occasionally responsible for great prolongation of the inflammation. In some cases a discharge is kept up by inflammation of the seminal vesicles (see page 1375).

Gonorrhea of the anus and rectum occasionally, though very rarely, occurs. It may result from pederasty, or in a woman from a flow of infectious material from the genitalia to the anus. It causes severe burning pain, aggravated by defecation. The parts are red, swollen, and tender. The discharge is profuse, being at first cream white, and then thicker and greenish. The diagnosis rests upon the history and the finding of gonococci in the discharge. The disease rarely extends above the anus. I have seen one undoubted case of rectal gonorrhea.

Treatment.—If the anus only is involved, spray it several times daily with peroxid of hydrogen, wash with salt solution, irrigate with permanganate of potash (1 : 4000), dust with talc powder, and interpose a piece of iodoform gauze between the inflamed surfaces. An ulcer, a fissure, or an excoriation is touched with lunar caustic. If the rectum becomes involved, secure a daily bowel movement and irrigate the rectum twice a day with boric acid solution or permanganate of potassium (1 : 4000).

Gonorrhea of the Mouth.—This is a very uncommon malady. It occurs in infants more often than in older people. Infection in infants may take place during birth if the mother has gonorrhea. The symptoms are those of violent stomatitis. The diagnosis is suggested by the condition of the mother and is proved by finding gonococci in the discharges from the mouth.

Treatment.—Wash the mouth frequently with boric acid solution, and swab the diseased areas at intervals with a 10 per cent. solution of argyrol.

Gonorrhea of the Nose.—It is alleged that this condition can arise, but an absolutely authentic case does not seem to be on record.

Gonorrhea in the Female.—There is much dispute as to the parts infected. Some observers maintain that the vaginal epithelium never contains gonococci and that gonococci found in a vaginal discharge have come from the cervix or uterine canal. Beyond a doubt, however, when young women who have not borne children contract gonorrhea the vulva and vagina usually suffer. In older women and in women who have borne children the vaginal tissues are altered and the cells are not nearly so prone to infection; hence in such subjects the vagina usually or at least often escapes. The initial infection is in many cases in the cervical canal, in some in the vulva or urethra. No matter what part was first attacked, other parts usually become quickly involved in the acute process. The urethra is involved in almost every case. Chronic gonorrhea is prone to linger in the urethra, in the glands of Bartholin, in the cervical canal, or within the uterus or in the Fallopian tubes. The great danger of gonorrhea in the female is the development of ascending infection of the lining membrane of the uterus, which may reach the tubes, ovaries, and peritoneum.

When infection occurs during pregnancy or when pregnancy occurs during infection of the cervical or uterine canal, abortion may take place. Again, a pregnant woman may not abort, but may go on to term and the child may receive a conjunctival infection during delivery and rapidly develop purulent ophthalmia.

In some cases when pregnancy occurs during the existence of gonorrhea the disease seems to pass away, and yet the child gets conjunctival infection during delivery or the mother subsequently develops pus-tubes.

Treatment.—Place the patient in bed during the acute stage of the disease, give hot hip-baths, keep the bowels open by means of saline purgatives, insist on a fluid diet consisting chiefly of milk, and flush out the urethra by having the patient drink considerable quantities of water. The external genital organs should be sprayed with peroxid of hydrogen every two or three hours, and after spraying should be dried with absorbent cotton and dusted with equal parts of starch and powdered oxid of zinc, or with powdered stearate of zinc. Pads of cotton fixed in place by a bandage are used to catch the discharge. If urethritis exists in this stage, we may give alkalis, balsams, and astringent urethral injections.

When the acute symptoms have somewhat abated an attempt should be made to prevent ascending infection from the cervical canal. The mucous membrane of the canal may be curetted away or be destroyed by pure carbolic acid or nitrate of silver. A wiser plan is to paint the cervical canal daily with iodin or a 10 per cent. solution of argyrol, painting the vaginal portion of the cervix at the same time with the same drug. The vagina is irrigated twice a day with a warm solution of permanganate of potash (1 : 4000) and is lightly packed with iodoform gauze. When the vulva is particularly involved, treat that part by applying acetate of aluminum (2 per cent.) locally or paint the vulva with silver solution (40 gr. to 1 oz.). If the vulvovaginal gland suppurates, open it.

If vaginitis exists and continues in spite of the treatment suggested above, wash out the vagina every two hours, first with 1 pint of hot solution of bicarbonate of sodium, next with 1 pint of hot water, and finally with 1 pint of astringent solution (1 teaspoonful of lead acetate, 1 teaspoonful of zinc sulphate, 1 teaspoonful of alum, or 4 teaspoonfuls of tannin to 1 pint of hot water). As the attack subsides, use vaginal suppositories, each containing

5 gr. of tannic acid. In some cases apply solutions of silver nitrate (1 : 200) or of argyrol (10 per cent.), and insert tampons of ichthyol (8 per cent.) moistened with boroglycerid (Le Blonde).

In chronic cases of urethritis use strong solutions of silver nitrate and irrigate the urethra and bladder with silver nitrate (1 : 8000).

For *uterine gonorrhea* observe the same general management. Swab out the uterus with tincture of iodin or nitrate of silver and insert tampons of iodoform gauze.

Gonorrhea in Children.—Male Children.—This disease is not very common. When it affects children under twelve it is usually due to some abandoned and diseased female having brought the child's penis in contact with her sexual organs. It may result from introducing infected materials into the penis. The symptoms are similar to, but more acute than, those met with in an adult. The finding of the gonococci is clinical but not absolute legal proof of the existence of gonorrhea, and it is to be remembered that boys may suffer from catarrhal urethritis as a result of introducing irritants, from balanoposthitis, or from overacid urine. Legal proof is afforded by the growth of the suspected micro-organisms on artificial blood-serum.

The *treatment* consists in confinement to bed during the acute stage, bland drinks, light diet, etc. Circumcision is necessary if phimosis exists. When the acute symptoms subside, injections are used as in an adult.

Female Children.—Gonorrhea is more common in female children than in male children, and the vagina is involved as well as the vulva and urethra.

A female child may suffer from catarrhal inflammation of the vulva, as a result of the contact of foul urine, of feces, of the presence of seat-worms, or of neglect of bathing. In such a case the vagina and urethra escape. Involvement of the vagina and urethra strongly suggests gonorrhea. A recently born child or a young infant may acquire gonorrhea directly from a diseased mother, or indirectly, by pus upon linen, from the mother's fingers, etc. A diseased nurse may infect the baby. Older children who have ceased to nurse may get the disease from infected linen, bathtubs, etc., and may by these means infect child after child in an institution. Now and then the disease arises by a diseased man or woman deliberately bringing the child's private parts in contact with their own diseased organ.

The disease is acute: the urethra, vulva, and vagina are usually involved; the discharge is profuse, purulent, and often bloody. During the first day or two the discharge exhibits leukocytes but no gonococci, and the normal flora of the urethra disappear; later gonococci appear (Harmsen, "Zeits. f. Hyg. u. Infektionskr.," 1906, vol. iii). Microscopical examination of the discharge is absolutely necessary. Dry cover-slip preparations are made so as to obtain clap shreds from the discharge. An attempt should be made to obtain cultures. The gonococcus is very difficult to maintain in culture; it must be frequently transferred, and it grows best in an incubator at a temperature of 36° C. No attempt is made to grow it upon ordinary culture-media. The finger may be sterilized and punctured, blood thus obtained being smeared upon ordinary agar. Upon this composite material growth can be obtained. Animal blood-serum is not a good medium, but human blood-serum is (Lehmann and Neumann). Human blood-serum is obtained by opening a vein or from a fresh placenta.

Lehmann and Neumann ("Atlas and Principles of Bacteriology") find the following a satisfactory medium: Agar, containing 1 per cent. peptone and 5 per cent. glycerin, which has been liquefied and cooled to 50° C., is mixed "with one-half its volume of ascitic fluid or the fluid from ovarian cysts." Plate cultures and streak cultures should be made. This excessive care in proving the presence of the gonococcus is imperatively necessary in

female children because of the medicolegal questions which may arise in such a case and also because of the danger there is of the case infecting other persons.

Surgeons are apt to be doubtful about the diagnosis in many supposed cases of gonorrhea in female children. The clinical picture may simply be that of catarrhal vulvovaginitis, it may be that of gonorrhea. The finding of the gonococcus is regarded as conclusive from a clinical standpoint, but not from the legal point of view. Again, as Taylor points out, in some cases in which the clinical and microscopical evidence seem to prove the existence of gonorrhea no proof can be obtained that the condition is of venereal origin, and that in some cases in which everything indicates that the disease began as a catarrhal vulvovaginitis, a condition seemingly identical with gonorrhea has arisen. Obtaining a culture of gonococci is conclusive. The treatment consists in taking every care to prevent diffusion of the infection to others and to the patient's own eyes. She is put to bed, given frequent baths, and fed upon milk, etc. Irrigations of bicarbonate of sodium are employed, followed by protargol (1 : 5000, according to White and Martin). Later astringent injections are indicated.

Treatment of Gonorrheal Arthritis and Endocarditis.—In a communication in the "Jour. Amer. Med. Assoc.," Jan. 27, 1906, pages 261–263, Messrs. Rogers and Torrey described the method of preparation of an antigonococcic serum for the treatment of gonorrheal arthritis. This serum in its present form, as manufactured by a good chemical company, seems possibly to be of some value in the treatment of gonorrheal infections of joints, tendon-sheaths, and allied structures. Dr. Thomas C. Stellwagen, of the Genito-urinary Department of Jefferson Hospital, has used the material in a series of 26 cases of acute and chronic gonorrheal arthritis with encouraging results ("Therapeutic Gazette," April 16, 1910, page 248).

Preparation of the Serum.—To quote from Messrs. Rogers and Torrey's reports (Loc. cit.): "Rabbits were at first used exclusively in producing the serum. Although a very potent serum may be obtained from these animals, it was found that the serum itself is decidedly toxic for some individuals and may produce a rather alarming reaction. In order to obviate this serious objection we have experimented with goats and sheep. Similar objectionable properties, although less in degree, were found to be present in goat serum, but from sheep serum they seem to be entirely absent. Accordingly in later work only these animals have been used. They should be full grown, uncastrated males. In immunizing these animals it has been found advantageous to pursue the following plan: The first inoculation may consist of the twenty-four-hour surface growth from 18 square inches of solid culture-medium, emulsified in about 30 c.c. of physiologic saline soution, and heated for one-half hour at 65° C."

In Stellwagen's studies and use of the serum it was found that the best results were obtained by giving the injections as close to the area of infection as possible, and, further, to give them every day. The only untoward results noticed were now and then an eruption of wheals or urticaria accompanied by slight headache and itching, with a trivial rise of temperature. The acute cases generally showed marked improvement after about the seventh injection. The serum also seemed to be of use in other complications, such as orchitis, prostatitis, and epididymitis. Stellwagen maintains that the serum is a valuable adjunct in treatment, especially where the older standard remedies are slow to produce a result. The great claim for serum, however, has been in arthritis and other synovial infections, in which it seems to be distinctly valuable.

The serum must not be confused with the vaccine, which is decidedly uncertain. When the vaccines were used in the venereal clinic of the Jefferson Hospital they did not produce the happy results that other clinicians

have claimed for them. Schäfer's gonorrheal phylacogen possibly furnishes a useful method of treatment for metastatic gonorrheal infections.

Stricture of the urethra, or narrowing of the urethral caliber, is divided into *inflammatory*, *spasmodic*, and *organic*. The so-called *inflammatory* or *congestive* stricture is not a stricture, but is an inflammatory swelling of the mucous membrane.

Spasmodic stricture does not exist alone, but complicates organic stricture, a hyperesthetic urethra, or an inflamed bladder.

Organic stricture is a fibrous narrowing of the urethra, due, as a rule, to chronic gonorrheal inflammation or to traumatism. True organic stricture is very rare in children, but can occur. Abbe reported a case of impassable stricture in the deep urethra of a male child two and one-half years of age, due to urethral gonorrhea. There were also two strictures of the anterior urethra. External urethrotomy was performed. Traumatic strictures occur in the bulbous or membranous urethra, and are due generally to force applied to the perineum, the urethra being squeezed between the subpubic ligament and the vulnerating body. Strictures resulting from gonorrheal inflammation occur in the penile, bulbous, or membranous urethra. Stricture never forms in the prostatic urethra except as a result of traumatism. Recent non-traumatic strictures are soft and are easily distended. Old strictures and traumatic strictures are very dense. A resilient stricture is one which contracts quickly after dilatation. The nearer a stricture is to the meatus, the more fibrous it is.

A *congenital* stricture is congenital narrowness of a portion of the urethra, usually the portion near the meatus. The more fibrous a stricture is, the more it narrows the urethra and the less dilatable it will prove. A stricture may be annular (forming a ring around the urethra), tubular (surrounding the urethra for a considerable distance), or bridle (when a band crosses the urethra from wall to wall). A stricture of large caliber will admit an instrument larger than a No. 15 French sound. A stricture of small caliber will not admit a No. 15 French sound. An impermeable stricture will not admit the passage of any instrument. "Impermeable" is more or less a relative term. A stricture may be impermeable when an anesthetic is not used, and permeable when the patient is anesthetized, or may be impermeable to one surgeon, but permeable to another. Impermeability is often a temporary condition due to spasm or to inflammatory edema about an organic stricture.

Symptoms and Results of Stricture.—There is usually a history of repeated attacks of urethritis. A chronic discharge may exist, the amount of which is variable. There is a feeling of weight in the perineum and soreness of the back, and frequency of micturition is complained of. Hypochondriacal tendencies are usual. In a deep stricture there is difficulty in starting the stream in micturition. In most cases the stream is small, twisted, and forked. There is often interruption or "stammering" of the stream, and it dribbles long after the conclusion of the act, so that the penis must be "milked" before it is returned within the clothing. The urethra back of the stricture dilates, a pouch forms, drops of urine collect and decompose, and a chronic inflammation results in the mucous membrane or the parts adjacent, which inflammation may go on to ulceration or to periurethral abscess. A urinary fistula results from the opening externally of a periurethral abscess. Retention of urine may occur, not from actual obliteration of the tube by the growth of the stricture, but by closure of the lumen of the urethra by muscular spasm and by edematous swelling in the neighborhood of the stricture. Edematous swelling may be due to cold, wet, venereal excitement, the use of alcohol, overexertion, etc. Spasm of the muscles results, and contact of the urine increases the spasm, and spasm plus edema of the mucous membrane closes

the urethra. Spasm may exist in the urethra itself and in the muscles of the neck of the bladder, but is only a temporary condition. In old strictures the bladder is hypertrophied and often fasciculated, and is very liable to cystitis. The diagnosis of stricture and of its location is made by the use of exploratory bougies. In this examination the author follows to a great extent the plan of Ramon Guitéras,[1] which is as follows: Have the patient pass urine into two glasses. Examine the urine for clap-shreds. Cloudiness in the first glass shows that urethral discharge exists. Cloudiness in the second glass points to cystitis. The patient is placed recumbent with his shoulders elevated, and the urethra is washed out with warm salt solution or boric acid. Bulbous sounds are inserted, beginning with No. 15 French. If this passes with ease, take a larger size and note where strictures are situated by the catch on withdrawal. If No. 15 does not pass, use a smaller size. Remember that the posterior layer of the triangular ligament catches a bulbous instrument on withdrawal. If the meatus is too small to permit of exploration, divide it by a curved bistoury, cutting from within outward. After cutting the meatus bleeding is arrested with styptic cotton, and a piece of absorbent cotton is tucked into the cut. After each act of micturition the patient inserts a fresh bit of cotton, and after three days the urethral examination may be proceeded with.

Treatment.—A stricture of large caliber in the deep urethra requires gradual dilatation. A steel bougie is introduced every fifth day, the size being gradually increased. Never anoint a bougie with vaselin, as it may become a nucleus for a stone in the bladder; use liquid cosmolin, glycerin, synol soap, or lubrichondrin. Before passing an instrument the patient urinates and his urethra is washed out with salt solution or boric acid solution. Glans, meatus, and urethra are cleansed as directed on page 1345. The sound is rendered sterile by boiling before using. Gradual dilatation can be effected by the use of the dilator of Oberlander, the tube being distended to the extent of 3 mm. every fifth day. If after dilatation there is urethral spasm, pain, or very frequent micturition, suspend the treatment for a number of days and order each night a hot hip-bath and a dose of paregoric. During gradual dilatation the patient should not use alcohol, should refrain from sexual excitement, should avoid cold and damp, and should take internally capsules containing boric acid and salol. It is rarely necessary to dilate above No. 32 French. After the surgeon finishes treatment he teaches the patient to use an instrument and directs him to pass it once a month, because gradual dilatation rarely cures a stricture, and if dilatation is permanently abandoned contraction will probably occur. Strictures in the pendulous urethra, if soft, are treated by gradual dilatation; if fibrous and contractile, by internal urethrotomy. For fibrous stricture in or near the bulb external urethrotomy should be combined with internal division. External urethrotomy secures drainage, and the doing of it greatly lowers mortality. In performing internal urethrotomy prepare the patient carefully; for several days before the operation give salol and boric acid by the mouth, and wash out the bladder repeatedly with boric acid solution. Be thoroughly aseptic. Anesthetize the patient. Before cutting irrigate the urethra with warm normal salt solution, and after cutting irrigate again, pass a rubber catheter into the bladder and tie it in. These precautions will prevent urethral fever. In cutting, insert Gross's urethrotome (Fig. 913) back of the stricture, spring out the blade, cut the stricture on the roof of the urethra, close the blade, withdraw the instrument, and pass a full-sized bougie.

Stricture of the meatus requires incision by a knife and the use of a meatus bougie until healing is complete. Strictures of small caliber in front of the

[1] "Med. Record," Nov. 14, 1896.

membranous urethra require gradual dilatation and, if this fails, internal urethrotomy or divulsion. Internal urethrotomy can be performed with the urethrotome of Maisonneuve (Fig. 914) or the Otis-Wyeth instrument (Fig. 916). The instrument of Maisonneuve is shaped like a sound, has a groove upon its surface, and into this groove a shaft carrying a triangular knife can be inserted. The staff is screwed to a guide, the guide is carried into the bladder and the staff

Fig. 913.—S. W. Gross's exploratory urethrotome.

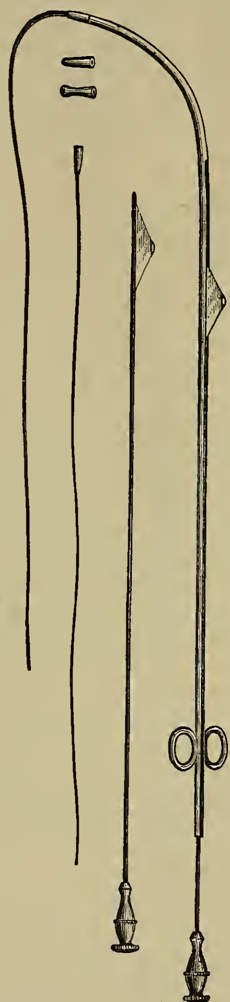

Fig. 914.—Maisonneuve's urethrotome.

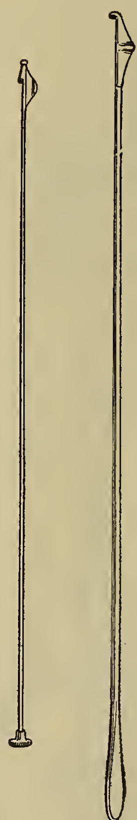

Fig. 915.—Horwitz's modification of Maisonneuve's urethrotome.

follows it. The point of the staff is carried to the prostatic urethra and the guide curls up in the bladder. The penis is held upon the stretch, the blade is inserted and pushed down through the stricture. This instrument cuts the stricture, but not the healthy urethra. Stricture within 1 inch of the meatus is divided on the floor of the urethra. A deeper stricture is divided on the roof, except at or near the bulbomenbranous junction. In such a stricture the roof is divided by internal urethrotomy and the floor by external urethrotomy. In

using a urethrotome do not overdilate or cut deeply. To do so will cause deformity of the penis. For *divulsion* the patient is prepared as for internal urethrotomy. The dilator of Gross (Fig. 917), or divulsor of Sir Henry Thompson or of Gouley (Figs. 918, 919) is introduced, the blades are separated, the instrument is withdrawn, a large bougie is passed, and a catheter is tied in the bladder. Strictures of small caliber in the deep urethra are seldon permanently benefited by gradual dilatation. The best method is combined internal and external urethrotomy. In strictures of the deep urethra, if only a filiform bougie can be introduced, the bougie may be left in place, and in a day or two another can be slipped in beside it, until in a few days the channel becomes permeable to a metal bougie. A tunneled catheter can be slipped over the filiform bougie, both be withdrawn, and a metal bougie passed. A tunneled and grooved staff can be carried in over the bougie and external urethrotomy be performed. Thompson's dilator can be carried in over the filiform and the stricture be divulsed. What is known as *modified rapid dilatation* consists in first dilating as described above by the Thompson dilator, then introducing the powerful dilator of Gross (Fig. 917) and distending the urethra to the limit. This operation tears and lacerates rather than dilates and has been practically abandoned. In impassable stricture of the deep urethra perform external perineal urethrotomy without a guide (the operation of Wheelhouse).

Fig. 916.—Otis's dilating urethrotome.

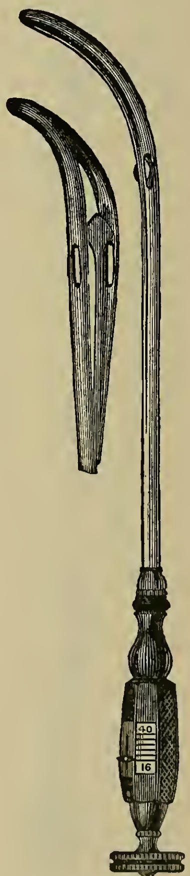

Fig. 917.—Gross's urethral dilator.

If a perineal fistula exists, dilate, divulse, or cut the stricture and retain a catheter in the bladder for forty-eight hours. After this period dilate the urethra every fourth or fifth day by a metal instrument. Every morning and evening draw the urine by a soft catheter, introduce boric acid solution into the bladder, remove the catheter, and let the man empty his bladder naturally. A part will flow from the fistula and a part from the meatus. Day by day the quantity which comes from the fistula lessens, and finally the abnormal opening heals.

Urethral Fever.—Any operation upon the urethra may be followed by a chill owing to shock (urethral shock), and this may be followed by a nervous fever. Urethral fever proper is sapremia following a urethral operation. The condition is due to absorption of toxic elements which may be in the urine, may have been in the urethra, or may have been introduced from without. It usually follows the first urinary act after operation. It begins with a violent chill and presents the characteristics of a septic fever. It is accompanied by a marked tendency to urinary suppression, and may eventuate

in septicemia or pyemia. Urethral fever can be prevented by rigid antisepsis. If this fever should arise, a catheter must be tied in the bladder, the bladder and urethra must be repeatedly irrigated with aseptic or antiseptic fluids, and the patient must be given urinary antiseptics and stimulants by the mouth.

Urinary Fever.—Sir Benjamin Brodie pointed out that the withdrawal of residual urine in a case of enlarged prostate may be followed by very serious symptoms. The condition is spoken of as urinary fever, and was said to be due to the sudden and complete emptying of a bladder which has become accustomed to retaining permanently a considerable quantity of urine. Modern studies prove that urinary fever is due to infection of the bladder and kidneys, and not simply to the sudden withdrawal of all of the urine from the bladder, although such a procedure leads to vesical con-

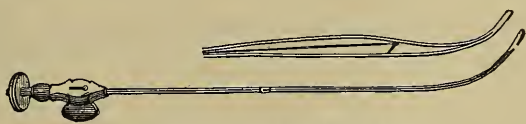

Fig. 918.—Thompson's divulsor.

gestion and probably favors infection. The bacteria most often found are pyogenic cocci, colon bacilli, and micro-organisms which cause putrefaction and decomposition of urea.

The condition does not arise promptly, suddenly, and violently, as does urethral fever, but begins rather insidiously after several days. Mr. C. Mansell Moullin[1] thus describes the condition:

"So far as the broader features are concerned, the symptoms that present themselves in these cases are remarkably uniform. They do not begin at once. Nearly always some few days elapse before there is anything to excite suspicion. Then the urine becomes cloudy, though it may still retain its acid reaction. A small quantity of albumin, more than can be accounted for by the amount of pus that is present, makes its appearance. Under the

Fig. 919.—Gouley's divulsor.

microscope there are a few hyaline casts, perhaps a blood-corpuscle or two, numerous pus-corpuscles, and myriads of bacteria. The specific gravity is lower than it ought to be, and is lower than it was before the catheter was used. The total amount passed in the twenty-four hours may either increase until it is as much as 7 or 8 pints, or diminish until it scarcely reaches 20 oz. There is seldom any definite rigor, but there may be numerous slight chills. The pulse grows more rapid and feeble. The tongue becomes red and dry. There is complete anorexia. Delirium sets in at night, and in a considerable proportion of cases the symptoms rapidly grow worse and worse until, at the end of a few days, the patient sinks into a semicomatose condition from which he seldom rallies. Postmortem there are all the signs of recent acute cystitis and pyelonephritis. The mucous membrane lining the pelvis

[1] "Lancet," Sept. 10, 1898.

and calices of the kidney, the ureters, and the bladder is swollen and stained by old and recent hemorrhages, and here and there a thin layer of pus is adherent to it. The pelvis and the ureters are dilated, the apices of the pyramids are eaten away, the cortex is shrunken and hard, the capsule is adherent, and in places between the tubules are minute collections of pus differing in shape and outline according to the anatomical arrangement."

Treatment.—Aseptic catheterization is necessary if we would avoid urinary fever; and as the urethra contains some of the causative organisms, the

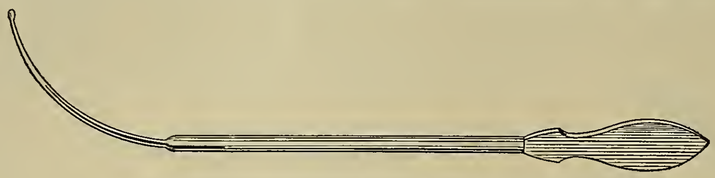

Fig. 920.—Syme's grooved staff.

prepuce, glans, and meatus should be washed with soap and water and irrigated with boric acid or permanganate of potassium solution, and the urethra be irrigated with boric acid solution or permanganate of potassium before the sterile catheter is introduced to draw the urine.

If urinary fever arises, it may be possible to control it by frequently irrigating the bladder with warm normal salt solution, solution of nitrate of silver (1 : 8000) or boric acid solution, and by administering stimulants,

Fig. 921.—Wheelhouse's staff.

diuretics, diaphoretics, saline cathartics, urotropin, salol or boric acid, quinin, and nutritious food. In severe cases perform suprapubic cystostomy for drainage.

Perineal section is external perineal urethrotomy. There are three methods—the operation of Syme, of Wheelhouse, and of Cock.

Syme's Operation.—This operation is employed if a stricture is very contractile, if dilatation fails to cure, or if urethral instrumentation invariably causes pronounced urethral fever. The patient is anesthetized, Syme's

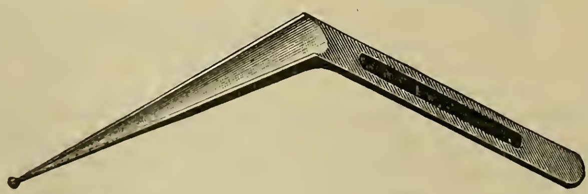

Fig. 922.—Teale's probe gorget.

staff (Fig. 920) is introduced, and the surgeon makes an incision in the midline of the perineum and exposes the staff just above the shoulder of the instrument. The knife is carried along the groove and divides the stricture. A catheter is passed into the bladder from the meatus and is retained for several days, and the wound is dressed antiseptically. After the catheter has been removed it must be used every six hours until the urine comes entirely by the meatus. During the rest of the patient's life a full-sized sound should be passed at monthly intervals.

Wheelhouse's Operation.—This operation is employed for the treament of impermeable stricture. Wheelhouse's staff (Fig. 921) is passed into the urethra until it blocks on the stricture. The perineum is incised down to the staff and in front of the stricture. The edges of the cut urethra are held apart by forceps, the surgeon seeks for the opening through the stricture, passes a fine probe through it, divides the stricture, carries into the bladder from the wound an instrument known as a probe gorget (Fig. 922) to dilate the canal and furnish a solid floor to facilitate the introduction of a catheter. With the gorget in place a metal catheter is carried from the meatus into the bladder. The gorget is removed and the catheter is tied in place. After three or four days the catheter is removed and is then passed frequently. The perineal wound is, of course, dressed antiseptically.

Cock's Operation.—This operation opens the urethra back of the stricture without the aid of a guide and relieves retention of urine. The surgeon introduces into the rectum the index-finger of the left hand, and the tip of the finger is rested upon the apex of the prostate gland. The surgeon incises the median line of the perineum, the back of the knife being toward the anus. When the point of the knife is felt to be near the finger the handle is lowered slightly, the blade is placed a little oblique, and the urethra is opened. A catheter is passed into the bladder from the wound and retained for a time, and the stricture is subsequently treated.

Gibson's Operation for Impermeable Stricture (C. L. Gibson, in "Med. Record," Aug. 6, 1910).—Open the posterior urethra by Cock's operation (see above). In most cases it is now possible to pass a small urethrotome from the urethral wound forward. If this can be done the deep stricture is at once divided. If it cannot be done a filiform is passed from the urethral wound out through the urinary meatus. This maneuver may require the aid of a special instrument (Gibson's retrograde filiform carrier). The straight staff of the Flühred urethrotome is threaded over the filiform bougie in front of the meatus. It is pushed back until it passes through the stricture, when the knife is inserted and "pushed home." This trivial cut permits the passage of a large urethrotome (for instance, Otis's). The stricture is now freely divided (up to No. 30 French). After division of the stricture a No. 30 French steel sound is carried from the meatus into the bladder. A tube to drain the bladder is introduced through the wound.

Epispadias is a congenital cleft in the corpora cavernosa, the roof of the urethra being completely or partly absent. In complete epispadias there are absence of the pubic arch and exstrophy of the bladder.

Partial epispadias may sometimes be remedied by a plastic operation.

Hypospadias is a congenital cleft on the floor of the urethra, the meatus opening on the floor at some point between the scrotum and the end of the glans penis, the channel in front of the meatus being a gutter and not a tube.

Hypospadias of the glans is the most common form. In this condition the urethra has no floor as it passes beneath the glans, the site of the urethra is indicated by a groove, and the foreskin is absent below. Partial hypospadias requires no treatment except possibly dilatation or incision of the meatus. People who suffer from it are very prone to develop chronic urethral inflammation. In hypospadias of the penis the ill-developed cord-like corpus spongiosum draws the penis to the scrotum. In this variety of the deformity the penis is very short.

In complete hypospadias the opening of the urethra is back of the scrotum in the perineum, the penis is dwarfed and bound down, and looks not unlike a clitoris, the scrotum is divided into two portions, a gap existing between them, and in many cases the testicles have not descended. Such individuals are occasionally mistaken for females. In the penile complete forms of

hypospadias a plastic operation should be performed between the eighth and tenth years of age. Such an operation, unfortunately, may fail. Hypospadias is rare in women, but it may occur. In such a case the urethra opens into the vagina. Figures 923–925 show the ingenious operation successfully practised by Carl Beck for penile hypospadias.

Chancroid (*soft chancre; the local venereal sore*) is an ulcer, usually of venereal origin. The name "chancroid" was introduced by Clerc, who believed that a soft sore resulted from inoculating a person already syphilitic with the products of a hard sore. He further held that when a soft sore arose the syphilitic poison lost its infective properties, and "could be transmitted as a soft sore to a healthy person, and not cause general infection."[1] The chancroidal ulcer is not connected with the syphilitic poison, but is developed by inoculation with the bacterium of Ducrey. Until recently it was believed that a chancroid was not produced by a special poison, but arose after in-

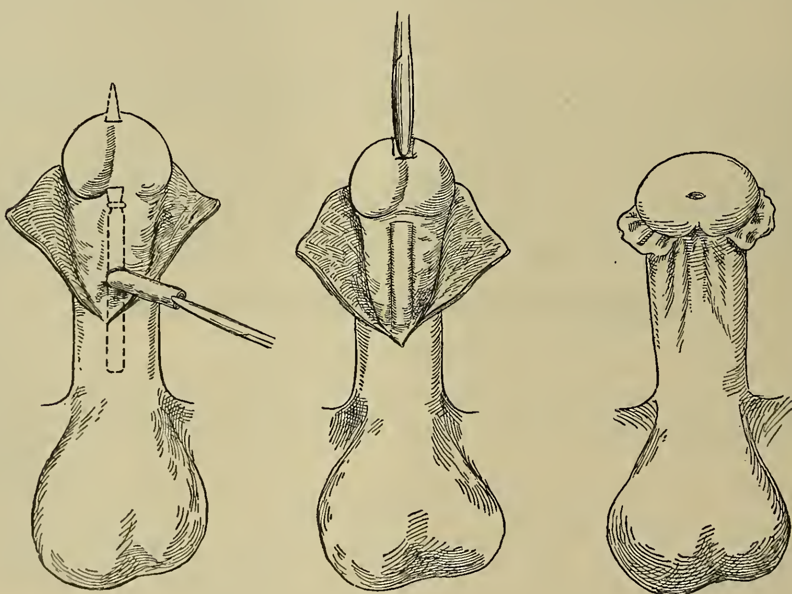

Fig. 923. Fig. 924. Fig. 925.

Figs. 923–925.—Beck's operation for hypospadias.

oculation with inflammatory products or irritating secretions. It seems to have been proved, however, by Krefting and Colombini that the organism discovered by Ducrey in 1889 is the real cause. This organism is grown on a medium of fresh blood and bouillon or in "unmixed human blood." (See Lincoln Davis, "Observations On the Distribution and Culture of the Chancroid Bacillus," "Report of Research Work," 1902–03; the Division of Surgery of the Medical School of Harvard University.) As a rule, chancroids are of venereal origin, and result from contact with other chancroids, pus, mucopus, or areas of ulceration. A chancroid appears soon after intercourse, usually within five days, always within ten days. It is first manifested by a pustule which ruptures and discloses an ulcer. This ulcer has sharply defined and undermined margins; it looks "punched out"; the base is gray and sloughy; the discharge is profuse, purulent, foul and auto-inoculable, and causes fresh chancroids by flowing over the parts. The area around a chan-

[1] "Syphilis," by Alfred Cooper.

croid is red and inflamed, and considerable pain is apt to be complained of. The original chancroid spreads and new sores appear. The edge of a chancroid is rarely indurated unless caustics have been used or there is mixed infection with syphilis. Inflammatory induration fades gradually into the tissues, but the induration of a hard chancre is sharply defined. Fournier says that a chancroid may have a hard base if the sore is located in the sulcus back of the glans, on a lip of the meatus, or on the lower border of the prepuce of a man with phimosis, or when the ulcer is inflamed. The surgeon should always ask if the sore has been cauterized and how it has been treated. When a chancroid after a time displays marked and sharply outlined induration it points to mixed infection with chancroidal and syphilitic organisms. Chancroids are not followed by constitutional symptoms, but are apt to be accompanied by painful inflammatory buboes which are prone to suppurate. In hospital practice about 30 per cent. of patients with chancroids develop buboes. The bubo may be either unilateral or bilateral. In the majority of cases the adenitis of chancroid is due to the absorption of toxins alone and the pus may be entirely free from bacteria. Cases have been reported in which non-indurated

Fig. 926.—Buttonhole perforation of the prepuce following phagedenic chancroid (Horwitz).

Fig. 927.—Buttonhole perforation of the prepuce following phagedenic chancroid (Horwitz).

sores were followed by syphilis. It is probable that a mixed infection existed, and that induration was overlooked, because a papular initial lesion was beneath the chancroidal ulcer. When inflammation in chancroids is high, a rapidly destructive ulceration known as *phagedena* may arise (Figs. 926 and 927), but this process is more common in syphilitic sores.

Treatment.—Ordinary cases of chancroid are treated by spraying with peroxid of hydrogen, drying with cotton, touching each sore first with pure carbolic acid and then with pure nitric acid, and dressing with black wash or dusting with iodoform or with calomel. Every few hours the patient soaks the penis in hot salt water (a teaspoonful of salt to a pint of water), sprays the sores with peroxid of hydrogen, dries with cotton, and dresses with black wash or dusts with iodoform or with calomel. As soon as granulation begins the sores should be dressed with 1 part of ointment of nitrate of mercury to 7 parts of cosmolin. Mild cases do well without cauterizing, peroxid of hydrogen being frequently used and a drying powder being employed. In chancroids with phimosis slit up the foreskin, smear the raw edges of the wound with pure carbolic acid, and treat the ulcers by cauterization. A regular circumcision usually fails because of infection of the stitch-holes. Phage-

dena requires the internal use of iron, quinin, and milk-punch, and the local use of powerful caustics (bromin or nitric acid or even the actual cautery). In some cases continuous antiseptic irrigation is valuable. When a bubo first begins, order rest, apply iodin or an ointment of belladonna or ichthyol, and make pressure by a spica bandage of the groin. Some surgeons advise the injection of 20 to 40 min. of a solution of carbolic acid (10 gr. to the ounce), but I have never seen any benefit from it. Some inject a 1 per cent. solution of bichlorid of mercury, but the proceeding causes intense pain. Welander recommends the injection of a 1 per cent. solution of benzoate of mercury. I have had no experience with this method. If the bubo persists though it does not suppurate, it should be completely excised. If pus forms, several methods of treatment are open to us: aspiration, injection with a solution of carbolic acid, squeezing out the acid and injecting 10 per cent. ointment of iodoform and glycerin, and sealing the opening with collodion (Scott Helms). Hayden makes a puncture, squeezes out the pus, washes out the cavity with peroxid of hydrogen, and then with corrosive sublimate solution, injects warm iodoform ointment, and dresses with cold, moist, corrosive sublimate gauze to set the ointment. Otis, Fontain, Perry, and others commend this plan. We have sometimes found it to succeed. If the above-mentioned plan fails, if it is not used, or if an ulcer or sinus exists, incise, curet, cauterize with pure carbolic acid, cut away hopelessly infiltrated skin, and pack the wound with iodoform gauze. In some cases it will be necessary to extirpate fragments of gland.

Phimosis is a condition of the prepuce that renders retraction over the glans impossible. It is usually congenital, but it may arise from inflammation. Congenital phimosis causes retention of sebaceous matter, which decomposes and lights up inflammation and the prepuce is apt to grow fast to the glans. Congenital phimosis may induce irritability of the bladder, incontinence of urine, prolapse of the rectum, and various nervous symptoms.

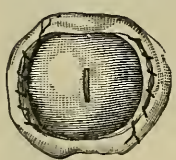

Fig. 928.—Circumcision completed (Esmarch and Kowalzig).

The **treatment** is *circumcision*. Asepticize the parts. Grasp the foreskin and the mucous membrane by two pairs of forceps, draw the prepuce forward, catch the skin (at the point it is desired to cut) horizontally between the arms of the handle of a pair of scissors, and cut off the redundant prepuce. Retrench the excess of mucous membrane by trimming with scissors $\frac{1}{4}$ inch from the glans, stitch the skin to the mucous membrane with catgut, and dress with sterile gauze (Fig. 928).

Fracture of the penis, which is a laceration of the cavernous bodies with extravasation of blood, occurs occasionally during coition.

The **treatment** consists of cold and bandaging to arrest bleeding, and in some cases incisions to let out clot.

Gangrene of the penis arises from phagedena, from tying constricting bands around the organ, from fracture with excessive hemorrhage, and from paraphimosis. If extensive, it requires amputation.

Cancer of the penis (Fig. 929) is commonest in persons with phimosis. In a limited epithelioma of the foreskin circumcision is performed and the glands of the groin are removed; if a well-developed cancer affects the glans, amputation of the penis is imperative and removal of the inguinal glands is absolutely necessary. Certain recent superficial cases without glandular involvement may apparently be cured by fulguration.

Amputation of the Penis.—Ricord advised cutting off the organ by a single stroke of the knife, making four slits in the mucous membrane of the urethra, and stitching each of these flaps to the skin. Treves splits the skin of the scrotum along the raphé, separates the halves of the scrotum

down to the corpus spongiosum, passes a metal catheter down to the triangular ligament, inserts a knife between the corpus spongiosum and the corpora cavernosa, withdraws the catheter, cuts the urethra across, detaches the urethra from the penis back to the triangular ligament, cuts around the root of the penis, divides the suspensory ligament, detaches each crus from the pubes, slits up the corpus spongiosum $\frac{1}{2}$ inch, stitches its edges to the rear end of the scrotal incision, introduces a drainage-tube, ligates the vessels, and sutures the wound.

Seminal Vesiculitis. — Inflammation of the seminal vesicles is due to the extension of a gonorrheal inflammation, to a pyogenic process, or to tuberculosis.

Acute vesiculitis is made evident by frequent and painful micturition, pains in the anus, rectum, and perineum, and possibly the hip-joint, back, and thighs. Defecation and micturition are excessively painful. Persistent erections may take place, and in some cases bloody ejaculations occur. Rectal examination detects the enlarged and tender vesicles external to the lateral lobes of the prostate and on a higher level.

Fig. 929.—Cancer of penis (Horwitz).

Treatment.—Abandon local urethral treatment, and treat the patient as for acute prostatitis.

Chronic vesiculitis may result from the acute form or may develop insidiously in an individual with gonorrhea. It is one of the possible causes of a chronic urethral discharge. The patient suffers from imperative and frequent demands to micturate, and he has a gleety discharge which becomes irregularly worse and better, but does not disappear. This chronic inflammation is believed to persist because of narrowing of the duct and consequent incomplete drainage of the vesicle. In chronic seminal vesiculitis there is usually sexual weakness, nocturnal emissions occur, and the semen may contain blood.

Fig. 930.—Dufaux's prostatic masseur.

Treatment.—Treat the posterior urethritis by ordinary methods. Use hot rectal enemata. Milk the ducts by Fuller's method once every seven days. During massage the patient's bladder should be full. He leans over a chair-back, the knees being straight and the body at a right angle to the thighs. The surgeon covers his finger with a rubber stall, anoints it with oil or synol soap, introduces it into the rectum, and makes pressure over the pubes with the fist of the other hand. The finger comes in contact with the lower half of the vesicle; it makes firm pressure for a moment and is then drawn slowly toward the duct. This stroking is repeated several times. The other vesicle is treated in the same manner. These maneuvers

empty the vesicles and hasten the resolution of inflammation. In many cases the finger reaches only the very lowest part of the vesicle. In such a case practice massage by means of Dufaux's rubber masseur (Fig. 930). After the completion of the stripping the patient should micturate, and the bladder and urethra should be irrigated.

Tuberculosis of the Seminal Vesicles.—Primary tuberculosis is very unusual. As a rule, there is evidence of antecedent tuberculosis of the testicle or prostate gland. About 50 per cent. of the cases occur in individuals under forty years of age. The diseased vesicle is at first nodular and indurated, but later undergoes caseation and softening. Finally the disease passes through the capsule and invades adjacent structures. Dreyer collected 36 cases and found that in 34 of them the lungs were involved.

Tuberculous vesiculitis may be unilateral or bilateral. In unilateral tuberculous epididymitis the corresponding vesicle is apt to become diseased. In bilateral disease of the testicles both vesicles are liable to become victims. Peritoneal tuberculosis may follow tuberculous vesiculitis. In very unusual cases spontaneous cure is obtained by fibrous-tissue formation. On palpation a tuberculous vesicle is found to contain here and there hard and but slightly tender nodules.

Treatment.—If tuberculous epididymitis is followed by tuberculous vesiculitis, it is justifiable to remove the vesicle after removing the epididymis or testicle, provided the prostate and other parts of the genito-urinary tract are free from disease and there is no distant lesion of tuberculosis. If both testicles or epididymes are removed, both vesicles can be extirpated. If a vesicle or both vesicles suffer from primary tuberculosis, operation is advised by some surgeons. Reported cases, however, do not seem to favor operation.

Kraske, Schede, and Rydygier have removed the vesicles after preliminary resection of the sacrum. Zuckerkandl, Diettl, and Schede have employed the perineal route. Villeneuve reached them by way of the inguinal region. The curved perineal incision of Zuckerkandl is the method usually preferred. H. H. Young makes a suprapubic incision, strips the peritoneum from the bladder, and reaches the vesicles from behind. He calls it the suprapubic-retrocystic-extraperitoneal method (H. H. Young, in "Annals of Surgery," Nov., 1901).

Acute Prostatitis.—Acute inflammation of the prostate gland may be caused by inflammation in adjacent structures, the use of instruments or irritant applications in the deep urethra, injury by a passing or impacted calculus, various infectious diseases, a stricture of the urethra, but particularly by gonorrhea. The gland enlarges greatly, the prostatic fluid exudes mixed with blood and pus, and the gland-ducts become distended with pus. A distinct abscess may form. The orifices of the ejaculatory ducts become distended and filled with pus, and the seminal vesicles or epididymes may also suffer. An abscess is liable to form in the cellular tissue outside of the prostate.

Symptoms.—There is a feeling of weight, fulness, or soreness in the perineum; a persistent pain at the neck of the bladder; frequent micturition, pain being present and becoming most severe as the last drops are voided; perineal tenderness; painful defecation; and bulging of the anal mucous membrane. If a finger is introduced into the rectum, it causes severe pain and palpates the enlarged and tender gland, unless the outlines are destroyed by periprostatitis, in which case there will be felt a large, boggy, tender mass. (See Henry Morris on "Injuries and Diseases of the Genital and Urinary Organs.") These symptoms are accompanied by distinct elevation of temperature. The inflammation may abate without suppuration, but, as a rule, pus forms, the temperature becomes characteristic, the pain becomes pulsatile, micturition

causes agony, the inflammatory mass is felt per rectum to be softening, and sometimes the swollen perineum becomes dusky red. Retention of urine is almost certain to occur. The abscess may rupture into the urethra or the rectum, or may diffuse in the periprostatic cellular tissue and subsequently may open in the perineum. Spontaneous evacuation may be followed by recovery or by the development of annoying or dangerous complications.

Treatment.—Keep a hot-water bag on the perineum and three or four times a day use rectal injections of hot water. Place the patient on a milk-diet. Leech the perineum. Give suppositories of opium and belladonna, and also suppositories of ichthyol, and administer urotropin by the mouth. Retention of urine is relieved by a soft catheter. When pus forms it may be possible in some cases to rupture the abscess into the urethra by the passage of a steel sound. If this can be accomplished it will be fortunate. Occasionally a specialist may succeed in opening the abscess through an operating cystoscope. Most cases require to be cut externally. What is known as the *boutonnière operation* is the method of choice. The patient is placed in the extreme lithotomy position. The index-finger of the left hand is introduced into the rectum and carried to the apex of the prostate. A straight bistoury is entered to the side of the median raphé and carried into the abscess cavity, and the opening is dilated by forceps. The urethra is not to be opened.

Chronic prostatitis may arise from stricture, venereal excess, chronic cystitis, or stone in the bladder, but gonorrhea is the common cause. The prostate is usually, but not always, enlarged, is somewhat softened, and the ducts contain pus and blood.

Symptoms.—There is usually a mucopurulent discharge or fluid can be obtained by massage of the prostate. There is a feeling of weight and fulness in the perineum, there is increased frequency of micturition, and the prostate is very sensitive to digital pressure. The patients are neurotic, frequently suffer from nocturnal emissions, and have but feeble power of erection. The prostatic urethra is extremely hyperesthetic. All the symptoms are aggravated by worry, sexual excitement, or violent exercise. An abscess may form and rupture into the urethra.

Treatment.—Tonics and nutritious food are essential. Intravesical irrigations with nitrate of silver solution (1 : 8000) do good. Massage of the prostate is useful. Some cases are benefited by touching the posterior urethra through a urethroscope tube with nitrate of silver (3 gr. to the ounce) or by injecting by means of Ultzman's syringe a few drops of silver nitrate solution (5 gr. to the ounce). Rectal suppositories of ichthyol may be ordered. Blistering the perineum at intervals may prove of service. At intervals of three or four days a full-sized cold steel sound should be gently introduced. If an abscess forms, open it through the perineum.

Prostatorrhea.—Just as overaction of the glands of the urethra constitutes urethrorrhea, so overaction of the glandular apparatus of the prostate gland constitutes prostatorrhea. Prostatorrhea is not inflammatory, although the prostate and posterior urethra are often congested, and the latter region is usually hyperesthetic. In some cases urethrorrhea exists with prostatorrhea. Prostatorrhea is produced by sexual excess, masturbation, ungratified sexual desire, riding a bicycle with an improper seat, and sometimes by riding horseback. The condition is usually accompanied by marked neurasthenia, and may be associated with spermatorrhea and impotence.

The patient notices a milky or gray discharge after straining at stool (*defecation spermatorrhea*), after violent exercise, sexual excitement, or a bicycle ride. The discharge also gathers in the urethra during sleep. Examination of the discharge shows it to be prostatic fluid, although spermatozoids are sometimes found. It is not purulent and contains amyloid cor-

puscles. The meatus is not glued up in the morning and the linen is very slightly stained. The urine is clear and contains small comma-shaped hooks. Sexual excitement and alcohol do not appreciably aggravate the condition. The bladder is irritable, and there is frequency of micturition and often some pain in the head of the penis at the termination of the act. Nocturnal emissions may occur.

Treatment.—The patient should correct bad habits. If there is urethral hyperesthesia or prostatic congestion, irrigate the bladder and urethra once a day with a solution of silver nitrate (1 : 4000), and every fourth or fifth day introduce a cold sound. In some cases the occasional instillation into the prostatic urethra of a few drops of a 1 per cent. solution of nitrate of silver does good.

For the irritable bladder give hot hip-baths at night. The following prescription is of service: 15 gr. of bromid of potassium, $\frac{1}{2}$ dram of tincture of hyoscyamus in $\frac{1}{2}$ oz. of cinnamon-water, three times a day. Hot enemata are of service.

After the hyperesthesia of the urethra has abated and nocturnal emissions have ceased, the neurasthenia is treated by cold sponging of the body night and morning, the continued use, at intervals of several days, of a large-sized cold sound, irrigation every second or third day with silver nitrate (1 : 4000), and the administration of strychnin and other tonics.

Hypertrophy of the Prostate Gland.—It was pointed out by Morgagni that in old men difficulty of micturition is due to obstruction by an enlarged prostate gland. Enlargement of the prostate gland may be brought about by different forms of growth. It is, as a general thing, a senile change, occurring only after the age of fifty, and being most likely to arise after the attainment of sixty years. It is very rare for enlargement of the prostate to cause symptoms long before the age of fifty or to begin after the age of seventy. Sir Henry Thompson maintained that 34 per cent. of men over sixty have prostatic hypertrophy, but that only half of them have troublesome symptoms. According to Freyer, 33 per cent. of all men past fifty-five years of age present some enlargement of the prostate.

There are some who oppose the view that prostatic enlargement is essentially a senile change. For instance, Dr. L. Bolton Bangs ("Jour. of Dermatol. and Gen.-urin. Dis.," March, 1901) maintains that the change is not senile; that it really begins early in life, but that its effects do not become manifest until during or after middle age. Lydston asserts that it begins during the third decade of life, but the gland does not attain sufficient size to cause symptoms till beyond middle life. Socin and Burckhardt, as a result of 300 postmortem examinations, reached the following conclusions: Between the ages of thirty-six and forty the gland is hypertrophied in 13 per cent. of cases, between forty and fifty in 25 per cent., between fifty and sixty in 31 per cent., between sixty and seventy in 56 per cent., between seventy and eighty in 50 per cent., and between eighty and ninety in 54 per cent. Undoubtedly, the enlargement begins long before it occasions sufficient obstruction to induce symptoms, and the growth progresses very slowly. Guyon and the French school in general maintain that hypertrophy of the prostate gland is always the result of arteriosclerosis, affecting not only the prostate, but also the entire urinary tract. The hypertrophy that ensues affects the bladder walls notably, as well as the prostate, because of distinct growth. Caspar has apparently demonstrated that Guyon's view is not correct. He has shown that in many cases there is no sclerosis of the prostatic arteries, and that frequently there are no sclerotic changes in other portions of the urinary tract. Another important point made by Caspar is that arteriosclerosis tends to cause degeneration, and not hypertrophy.

Some think that sexual excess is a cause of prostatic enlargement; some

assert that antecedent gonorrhea is the cause, but it seems very improbable that either is causal. Belfield blames altered testicular secretion; Hawley believes the cause to be altered prostatic secretion and the "chemical action of pathological proteins resulting from irregular metabolism or derived from disintegration of the secretion, or in the usual action of tissue enzymes" ("Annals of Surgery," Nov., 1903).

In the hypertrophied prostate there is an excessive production of fibrous tissue and of ill-formed glandular tissue, the mass constituting a fibro-adenoma. Fibro-adenoma is the common cause of enlargement (W. Bruce Clarke). Typical adenoma, according to Albarran and Hallé, is found in 14 per cent. of the cases ("Annales des Maladies des Organes Génito-Urinaires," Feb. and March, 1900). Again, in not a few prostates there is no real enlargement, but there is an indurated fibrous mass producing obstruction. Albarran and Hallé (Ibid., 1898, vol. xvi) point out that in an enlargement of the prostate different elements may usually be recognized: soft hypertrophy of the gland; indurated enlargement of the glandular elements; fibrous enlargement; circumscribed tumor-masses; distinct fibromata or myomata; or adenofibromyomata. The real cause of the various forms of prostatic enlargement is not known. Nearly 10 per cent. of cases are cancerous (Oraison), and adenoma is apt to be transformed into cancer.

All the lobes may be enlarged equally; all may be enlarged unequally; the enlarged gland may surround the prostatic urethra like a horse-collar; or one lobe only may be enlarged. Symmetrical enlargement of the entire gland is not so apt to produce symptoms as is non-symmetrical enlargement. In some cases the chief enlargement is into the bladder; in others, into the urethra. An enlarged prostate frequently shows a circular groove about it, due to the constriction exerted by the rectovesical fascia at the vesical neck.

The bridge of prostate which joins the two lateral lobes behind the urethra is known as the *lobe of Home* or the *middle lobe*, and a comparatively trivial enlargement of the middle lobe may cause obstruction. Prostatic hypertrophy causes narrowing and lengthening of the urethra, and gives this tube a tortuous course. The opening of the urethra into the bladder is usually pushed to a higher level, and there forms behind it a pouch in which urine collects. The urine that gathers in this pouch is known as *residual urine*. It cannot be voluntarily expelled. It may, therefore, collect in large quantity, and it is likely to decompose, producing cystitis. Residual urine strongly favors calculus formation. The mechanical resistance to the expulsion of the urine causes congestion of the neck of the bladder and the posterior urethra and also hypertrophy of the muscles of the bladder. In consequence of the hypertrophy the bladder enlarges, thickens, and becomes fasciculated. When this takes place, micturition becomes very difficult and sometimes impossible. Enlargement of the middle lobe inevitably blocks the flow of urine and causes great distention of the bladder. In hypertrophy of the prostate gland the ureters and the renal pelves and calyces may distend and surgical kidney may develop.

It is useful to divide persons with prostatic hypertrophy into three groups: (1) those in whom there is no obstruction or in whom the urinary symptoms are very trivial; (2) those in whom there are residual urine and disturbances of urinary function, who depend upon the catheter for relief, but who do very well by this method; and (3) those that suffer a complete breakdown during the period in which the catheter is depended upon (Orville Horwitz, in "Phila. Med. Jour.," Nov. 16, 1901).

Symptoms.—In 90 per cent. of the cases there is very trivial inconvenience, the patient merely being annoyed somewhat by episodes of nocturnal frequency of micturition. The stream of urine is slow to start and falls feebly

from the end of the penis. In some cases there is interruption of the stream (stammering). The last drops fall entirely without control. If the patient becomes sexually excited, chilled, or worried, or indulges inordinately in the pleasures of the table or in wine, beer, or alcoholic liquors, nocturnal frequency of micturition becomes for a short time most harassing. In 10 per cent. of all cases the bladder cannot be emptied entirely, and residual urine collects. Frequency of micturition comes on, particularly at night; the patient has to get up often; the bladder never feels empty; and cystitis is apt to arise. The urine, at first acid and clear, becomes neutral and cloudy, and finally ammoniacal and turbid, and contains bacteria, mucopus, precipitates of phosphates, and blood. Above the pubes there is aching pain, soon spreading to the perineum, which pain is increased when the bladder is distended and during micturition. The rectum becomes irritable, and piles form or prolapse of the mucous membrane occurs, because of straining in micturition. Attacks of retention of urine may occur. In about one-third of all cases we can make a diagnosis by rectal palpation. In enlargement of the middle lobe alone or in pure intravesical enlargement rectal touch will fail to make the diagnosis and the cystoscope must be relied upon. The bladder becomes thin and distended, or hypertrophied, rigid, and fasciculated. In rare cases true incontinence is caused by the median lobe growing toward the neck of the bladder and preventing closure. The health breaks down because of pain, restless nights, indigestion, and disorder of the bowels. The kidneys may become involved (inflammation of the pelves or calices, or surgical kidney) and suppression may occur. Septic fever may arise. Calculi may form in the bladder. Death is due to exhaustion, suppression of urine, or septic cystitis. A foul catheter is the usual cause of septic cystitis, but micro-organisms sometimes enter by passing along the urethral mucous membrane.

A patient should be examined by rectal touch, by a sound, and by a cystoscope, if possible; the amount of residual urine must be determined, and the condition of the urine is to be carefully studied. The presence or absence of stone should always be determined. After an examination by instruments the patient must remain in bed for twenty-four hours.

Treatment.—There is no known method of preventing prostatic hypertrophy. Many cases of enlargement are treated by regular catheterization, and if this is conducted with careful cleanliness, and if the patient rigidly adheres to hygienic rules, he may be kept comfortable in this way for a considerable time. When a man must depend upon a catheter to empty his bladder he is said to be in *catheter life*. Alexander has formulated several sound rules as to when catheterization is the proper treatment. He says, if the patient is intelligent and dextrous, if cystitis is not severe, if the amount of residual urine is not very large, if obstruction is not great, if the bladder retains considerable expulsive power, and if catheterization is easy and painless, we are justified in relying upon this simple plan of treatment. Prevent cystitis by emptying the bladder each evening with a coudé catheter. If there is trouble in passing the catheter, strengthen the instrument by inserting a filiform bougie as a stylet. It is very seldom that a metal instrument is required, but if it is necessary, a catheter with a large curve is employed. If a soft or semisolid instrument can be passed, teach the patient how to clean it, how to use it, and how to keep it, but never permit the patient to use a metal instrument himself. A dirty instrument may cause fatal infection. It is true that some people use dirty instruments for long periods without trouble, but in most cases there will be trouble if it is attempted. It is absolutely necessary to use only perfectly aseptic instruments. Metal instruments are sterilized by boiling in water. Rubber catheters can be cleansed by washing with soap and running water, wrapping in gauze, and boiling. After

sterilization the instruments are kept ready for use in a glass cylinder which contains calcium chlorid.[1] The cleansing of catheters is discussed on page 1311. If there are 3 oz. of residual urine, use the catheter only at night. If there are 6 oz., use it night and morning. If there are more than 6 oz. of residual urine, add one more catheterization a day for every additional 2 oz. present until the catheter is used six times in the twenty-four hours. It should never be used oftener than this. Gradual dilatation with steel sounds is of benefit, but forcible dilatation is not advisable. The sound may be passed once a week. Tell the patient to avoid violent exercise, cold, damp, sexual excitement, and the use of alcoholic liquors; prevent constipation and indigestion, and direct him to drink milk and plenty of water. A hot hip-bath at night adds to his comfort. Hot enemata are of value. If a large quantity of residual urine exists, or if cystitis begins, wash out the bladder daily with boric acid solution, or normal salt solution, or nitrate of silver (from 1 : 10,000 to 1 : 4000), and give urotropin or salol and boric acid by the mouth (see Cystitis, page 1324). In some severe cases, if a large-sized rubber catheter be tied in the bladder for a few days, great relief is obtained. Retention of urine can usually be relieved by the introduction of a coudé catheter strengthened with a whalebone. In exceptional cases a silver instrument with a prostatic curve must be employed or aspiration must be practised. Many cases occurring among well-to-do people can be kept comfortable by catheterization. Some surgeons still think that only when this fails should an operation be performed. Unfortunately, sooner or later a man who regularly relies upon the catheter will develop cystitis. A poor man cannot give the necessary time and attention to make catheter life safe and operation must be thought of in him sooner than in others. If the symptoms grow constantly worse, if the suffering becomes severe, if the patient cannot urinate without the use of an instrument, if catheterization is painful or impossible, if the patient is too careless or ignorant to trust with a catheter, if only a catheter of very small size can be introduced, if attacks of obstinate retention occur, if there is persistent or recurring cystitis or hematuria, if there are signs of beginning infection of the kidney, if the residual urine gradually increases in amount, operation is called for. Do not postpone operation until the patient becomes really ill. Give palliative measures a reasonable trial, and if they fail, operate. Before determining upon any operation make a cystoscopic examination. This is particularly valuable before a Bottini operation and before a perineal operation. It shows us the condition of the bladder; the nature, size, and situation of the enlargement, the median lobe if present, and a calculus if one exists. This examination may determine the form of operation desirable. Prostatectomy is not to be regarded as a trivial affair certain to result in cure. It is a grave procedure, with a considerable mortality, which may be attended by disastrous complications and from which unfortunate consequences may arise. I agree with James E. Moore that "it is altogether too grave an operation to be resorted to as a routine treatment for every enlarged prostate, and is applicable only to properly selected cases." The operation is contra-indicated if there is advanced disease of the kidneys, and if it is performed in such a case, fatal uremia is to be expected. Age is not in itself a contra-indication if the kidneys and cardiovascular system are sound. An occasional sequel of prostatectomy is incontinence of urine due to injury of the neck of the bladder or to the nerves of the part. A possible sequel is sterility, but most of the subjects have been rendered practically sterile before operation by age.

In the majority of cases in which palliation fails the operative indication is to remove an obstructing mass and depress the level of the opening from the bladder into the prostatic urethra, so that the prostatic pouch is abol-

[1] R. W. Frank, in "Berliner klin. Woch.," No. 44, 1895.

ished and the bladder can be thoroughly drained. The surgeon chooses between prostatotomy and prostatectomy. Prostatotomy is usually performed by the galvanocautery (Bottini's operation). Prostatectomy may be suprapubic or perineal, and the latter may be by enucleation without the aid of sight (as in the operations of Nicoll and Alexander) or by open dissection (as in Young's operation). No one routine plan is suitable for all cases. The patient should be studied, and the operation chosen which is safest and best for that individual case. The surgeon who only uses one method must wrong many patients, and he retains consistency at the expense of humanity. It was formerly believed that any operation of total prostatectomy must of necessity produce impotence. This we now know need not be the case. The suprapubic operation is proabaly less likely to be followed by this than is the perineal, as it usually spares the ejaculatory ducts. Young's perineal operation spares the ejaculatory ducts. Destruction of the ejaculatory ducts certainly produces sterility and may, but does not of necessity, produce impotence. Willy Meyer ("Med. Record.," Oct. 7, 1905) points out that impotence may be caused by damaging important nerves or blood-vessels in advancing through the perineum, and also by the operation producing relaxation of the verumontanum and prostatic urethra, parts necessary in the reflex for erection.

The *perineal operation* is as safe as the suprapubic or safer, and can be rapidly performed. It is the desirable route when the gland can be palpated per rectum, and does not mount high up when we are dealing with the early stages of soft hypertrophy (Willy Meyer, Ibid.) and when prolonged drainage is required. According to Francis S. Watson ("Annals of Surgery," June, 1904), the mortality in 203 cases was only 2.9 per cent. In 563 cases of removal through the perineum by dissection the mortality was 5.5 per cent. Young's cases in this group number 150 and his mortality was 4.6 per cent.; the mortality of Hartman was 9 per cent.; of Albarran, 4 per cent., and of Murphy, 3.9 per cent. (Schachner, in "Annals of Surgery," August, 1908). In 190 cases of blind enucleation through the perineum the mortality was 4.7 per cent. (Ibid.).

After the performance of the perineal operation the drainage is at the lowest part of the bladder. In a perineal operation every effort should be made to do as little damage as possible to the urethra. If we destroy the entire prostatic urethra the operation becomes easy and rapid and Nature rapidly repairs it, but a traumatic stricture may follow and may make the patient's condition worse than at first. As Moore says, we must destroy a portion of the floor of the urethra, but we can preserve the roof and the side walls. Another point in the perineal operation is to avoid injuring the rectum. A tear may enter the rectum, or, even if the gut was not torn, sloughing of the rectum resulting in recto-urethral fistula may occur. The rectum may be opened because the surgeon fails to stick close to the urethra in his dissection, and sloughing may be due to an injudicious use of the retractors. If the rectum is opened, it should be at once sutured with catgut. In most cases it takes about three weeks for the wound in the perineum to heal, and in some few cases a perineal urinary fistula is established. Urinary incontinence may follow this operation. By simply incising the prostate gland the floor of the urethra may be lowered to the level of the floor of the bladder. Simple incision of the prostate in this manner, or by Bottini's method, is known as *prostatotomy*. The mortality is small and the relief is often great. Prostatotomy is performed on old and exhausted patients with damaged kidneys. A large tube should be worn during the healing of the wound.

The *suprapubic operation* is easier than the perineal; it is less safe; it gives excellent results if temporary drainage only is needed. According to Watson ("Annals of Surgery," June, 1904), the mortality in 69 cases was 8.6 per cent. P. J. Freyer reports 600 cases varying in age from forty-eight to

eighty-nine years. There were 47 between the ages of eighty and eighty-nine, and 7 were seventy-nine; most of the cases had been entirely dependent on the catheter for periods up to twenty-four years. "Nearly all were in broken health and many apparently dying before operation. Few were free from one or more grave complications, such as cystitis, stone in the bladder, pyelitis, kidney disease, diabetes, heart disease, chronic bronchitis, paralysis, hernia; and in a few instances there was malignant disease of some other organ than the prostate" ("Archives Internationales de Chirurgie," vol. iv, Fascic. 4, 1909). In these 600 cases there were 37 deaths in periods of from six hours to thirty-seven days after operation, a mortality of 6.15 per cent. Suprapubic prostatectomy is indicated in rather young subjects in whom we greatly fear impotence; in cases in which the gland is placed high; in cases in which the gland is not palpable per rectum, but is causing serious symptoms, and in which the hypertrophy is recognized by the cystoscope (Meyer); in cases in which there is a middle lobe; in cases in which cancer exists, or in which calculus complicates the case. It is the most useful operation when the gland is very large and intravesical. It is not a suitable method if the bladder is markedly contracted or if the belly walls are very thick. If prolonged drainage (short of permanent drainage) is required, as it is sure to be in cases with advanced cystitis, the opening is better placed in the perineal operation. If when a suprapubic operation has been performed it is found that prolonged drainage is indicated, a siphon drain (Fig. 886) may be used. If permanent drainage is required in a case, the suprapubic method is the best. After a suprapubic cystostomy has been performed for drainage, the opening may be kept permanently patent by the retention of a tube (Hunter McGuire's operation). It is only in very advanced cases or in cancer that permanent suprapubic drainage is employed. After making a suprapubic incision the floor of the urethra cannot be brought level with the floor of the bladder by a simple incision of the prostate through this incision; it can be brought level only by the performance of prostatectomy. In the suprapubic operation the structures divided are less important, the hemorrhage is less, and the drainage is less conveniently placed but better than in the perineal operation. Suprapubic prostatectomy inflicts injury upon the bladder, it may gravely damage the sphincter of the bladder, and is sometimes followed by incontinence or by inability to expel urine (John B. Murphy, "Jour. Amer. Med. Assoc.," March 29, 1902), but disturbance of control is less common than after the perineal operation. The bladder wall may be seriously torn, and if such a wound should be inflicted, it ought to be sutured with catgut. In this operation if the bladder is contracted, the surgeon must exercise great care to avoid injuring the peritoneum. The ureters may be damaged and subsequently become obstructed from contraction. If death occurs after prostatectomy it is due to shock, uremia, sepsis, or postoperative complications, usually pulmonary. Schachner ("Annals of Surgery," August, 1908) uses Watson's figures to present the special dangers of each operation. The figures give the percentage of the deaths due to shock, uremia, hemorrhage, and pulmonary complications. The table is as follows:

	Per cent.	Cause
Bottini	2.7	Uremia (or renal insufficiency).
Perineal operations	35.0	Uremia (or renal insufficiency).
Suprapubic operations	34.0	Uremia (or renal insufficiency).
Bottini	52.0	Sepsis.
Perineal operations	17.8	Sepsis.
Suprapubic operations	8.6	Sepsis.
Bottini	5.0	Shock.
Perineal operations	21.4	Shock.
Suprapubic operations	30.0	Shock.
Bottini	8.0	Postoperative pulmonary complications.
Perineal operations	17.8	Postoperative pulmonary complications.
Suprapubic operations	22.0	Postoperative pulmonary complications.

At the International Urological Congress held in London in 1911 Young presented the records of 484 cases of perineal prostatectomy. The mortality in simple hypertrophy (450 cases) was 3.77 per cent.; 34 cases were cancerous, and of these 2 died. Zuckerkandl's mortality from perineal operations was 9.5 per cent., from suprapubic operations, 18.7 per cent. ("Ann. des Mal. des Org. Gén.-Urin.," 1911, ii). Freyer ("Amer. Jour. of Dermatology and Genito-Urinary Diseases," 1912) reports 1000 cases of suprapubic prostatectomy since 1901. The average age of these cases was sixty-nine. The youngest patient was forty-nine, the oldest was ninety. There were 55 deaths (a mortality of 5.5 per cent.). Freyer's mortality in his first 100 cases was 10 per cent., in his last 100 cases it was 3 per cent. This proves the great value of experience. The less training a man has had, the higher will be his mortality. Prostatectomy is distinctly not an operation for a surgical juvenile.

Suprapubic Prostatectomy.—Freyer's Method.—The bladder is washed out through a catheter with warm boric acid solution and is then filled with the solution. The nozzle of a large syringe filled with fluid is inserted into the end of the catheter. This keeps the bladder fluid from running out and enables the surgeon to quickly distend the viscus more if occasion shall arise. The bladder is exposed and opened in the midline and in an area free from veins (see Suprapubic Cystotomy, page 1337). The incision is vertical, is made toward the symphysis, and is about 1 inch in length (it can be enlarged later if necessary). If any calculi are found they are at once removed. A finger is placed in the rectum to raise up the prostate and keep it steady. The finger of the other hand is introduced into the bladder, and by means of the finger-nail the mucous membrane is scratched through over "the most prominent portion of one lateral lobe, or over the so-called middle lobe, if there be but one prominence" (Freyer, in "Archiv. Internat. de Chir.," Fascic. 4, 1909). This portion of the gland is only covered by mucous membrane, and when this is scratched through the true prostatic capsule is reached. In doing Freyer's operation the author passes the finger to the extreme anterior limit of the trigone, so that the finger is really within the urethra. At this point he splits the capsule and begins the enucleation, being careful to injure the trigone as little as possible. This precaution greatly lessens the danger of incontinence. The finger is kept in close contact with the true capsule and enucleates the gland by passing first posterior, next outside, and finally in front of one lateral lobe.

"The finger is then swept in a circular fashion from without inward, in front of and to the inner side of the lobe, detaching this from the urethra, which is felt covering the catheter, and pushed forward toward the symphysis between the lateral lobes, which will, as a rule, have separated along their anterior commissure in the course of the manipulations. The other lobe is attacked and treated in the same manner. The finger is next pushed well downward behind the prostate and the inferior surface of the gland is peeled off the triangular ligament. When the prostate is felt free within its sheath and separated from the urethra, with the finger in the rectum, aided by that in the bladder, it is pushed into the bladder through the opening in the mucous membrane, which, during the manipulations, will have become considerably enlarged" (Freyer, Ibid.). The prostate is removed from the bladder by forceps. If the lobes come away separately, Freyer believes that the ejaculatory ducts are uninjured and remain attached to the urethra. There has been an active controversy as to whether Freyer's operation does or does not destroy the prostatic urethra. It seems certain that even if it is left it must slough for want of blood-supply. In my operations by this method it has come away with the prostate.

In Freyer's earlier operations he sought to leave the urethra and accom-

panying structures behind, but he is now convinced that the prostatic urethra may be torn or removed without ill results. Figure 931 shows the drainage as I employ it after suprapubic prostatectomy. Figure 932 shows the drain.

McGill's Operation.—The bladder is opened by a suprapubic incision, the edges of the cut bladder are sutured to the abdominal wound with catgut, and the interior of the viscus is carefully explored by the finger and by sight, an electric light being used for illumination. If a sessile growth exists, the mucous membrane is incised and the growth enucleated by finger or a curet. A pedunculated growth is cut away by sharp-edged forceps. If a mass projects into the bladder, an incision is made to divide it into two portions and each half is enucleated. Hemorrhage is arrested by irrigation with hot salt solution and by compression with gauze pads. In some cases a tampon must be inserted. The bladder is drained for several days or a number of days. As a matter of fact, a dense fibrous prostate cannot be enucleated and can be removed only by scissors or cutting forceps.

Fuller's Operation.—Open the bladder above the pubes; have an assistant push the gland up by means of a fist in the perineum. The gland can be

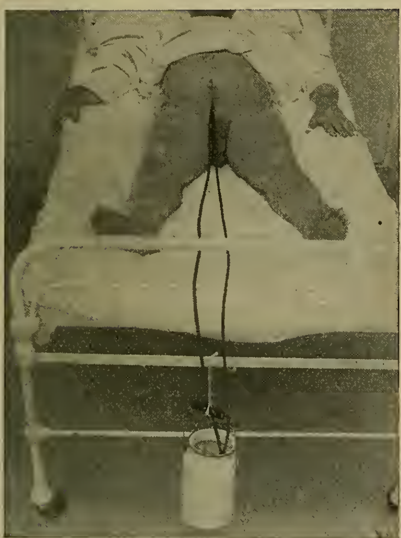

Fig. 931.

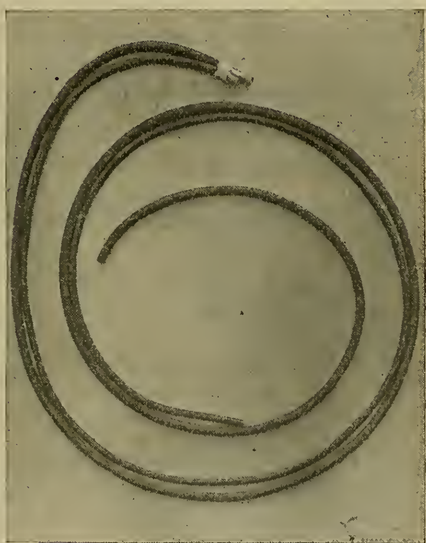

Fig. 932.

Figs. 931 and 932.—Showing double-tube drainage for suprapubic operation. Fig. 931 was taken from an elevation to show the termination of the drainage-tubes. Fig. 932 shows tubes enlarged in separate view.

lifted by two fingers in the rectum. The surgeon makes a small incision through the mucous membrane over the prostate, enucleates the gland by means of the finger, and drains through an incision in the membranous urethra, as well as through the suprapubic opening.

Belfield's Operation.—Belfield performs suprapubic cystotomy, makes a perineal cut to enable the finger to approach the prostate, pushes the prostate up toward the belly, and enucleates it from within the bladder.

Perineal prostatectomy is less bloody than suprapubic prostatectomy. The sphincter of the bladder is not damaged, the entire prostate can be brought into view and removed, and perfect drainage is obtainable after operation.

Nicoll's Operation.—Perform suprapubic cystotomy. Then incise the perineum down to the prostate, split the capsule of the prostate, insert two fingers of the left hand into the bladder, and push the prostate into the perineum so

as to bring it within reach. Enucletae the gland from the perineal wound without damaging the mucous membrane of the floor of the bladder.

Alexander's Operation.—Alexander makes a suprapubic incision and uses it for the same purpose as does Nicoll, but he also opens the membranous urethra on a grooved staff. After enucleating the gland he inserts a drainage-tube through the incision in the membranous urethra. In a very thin subject it may not be necessary to perform suprapubic cystotomy. Alexander has brought the gland into an accessible position in the perineal wound by suprapubic pressure, and Guitéras has done so by making an incision in the linea alba and inserting two fingers into the prevesical space. Syms advocates opening into the peritoneal cavity, inserting the hand, and pressing the prostate into the perineum without opening the bladder above the pubes.

Bryson's Operation.—This is a satisfactory method in some cases. The bladder is irrigated and filled with warm salt solution. A grooved staff is introduced and a median perineal section is made to open the urethra just in front of the apex of the prostate gland. The knife is pushed back in the groove of the staff sufficiently far to incise the ring at the apex of the prostate; the forefinger is passed into the prostatic urethra and the staff is withdrawn. Then a short tear is made by means of a blunt instrument into the mass of the left lobe and the finger is introduced and enucleates the lobe. The same procedure is carried out on the right lobe, and, finally, if necessary, on the middle lobe. If the middle lobe requires removal, but cannot be reached, a suprapubic cut is made into the cave of Retzius, two fingers are inserted, and the lobe is pushed within reach of the finger below. A large perineal tube is introduced for drainage, a catheter is introduced and tied in place, and bleeding is arrested by packing.

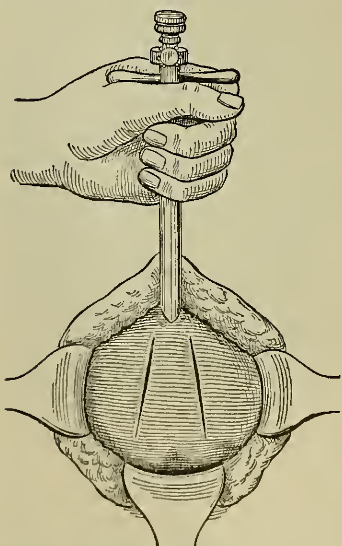

Fig. 933.—Tractor introduced; blades separated; traction made, exposing posterior surface of prostate. Incisions in capsular on each side of ejaculatory ducts (Young).

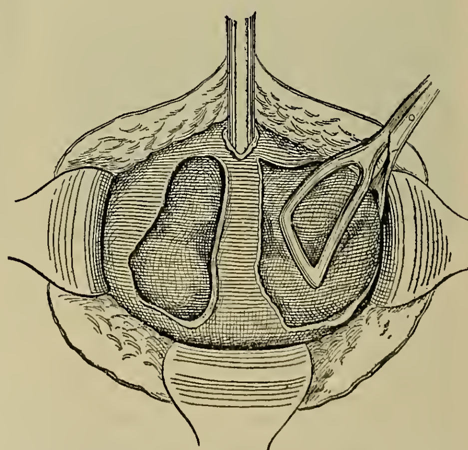

Fig. 934.—Enucleation of lobes. Forceps in position (Young).

Young's Operation.—This surgeon frequently operates under spinal anesthesia. He places the patient in an exaggerated lithotomy position and introduces a sound. In thin subjects the incision is in the raphé and is carried close to the anus; in short individuals the incision is an inverted V. He incises the recto-urethralis muscle transversely, exposes the membranous urethra, opens it, and inserts his tractor into the opening in the urethra (Fig. 933). The tractor is turned 180 degrees, the blades are opened, and traction is made.

The capsule is incised on each side of the ejaculatory ducts and the gland is removed by blunt dissection, the forceps grasping each lobe during enucleation (Fig. 934). Every effort is made to save the urethra. After removing the lateral lobes the tractor is used to bring a middle lobe, if one exists, into the wound, and it is also enucleated. The bladder is drained for about one week.

Young's punch operation was devised for the removal of small prostatic bars and contractures of the vesical neck involving the prostate. Young reports 200 cases with no mortality. It can be done under local urethral anesthesia; 4 per cent. novocain is employed. The operation is performed by means of a special prostatic punch devised by Young. By means of the punch a portion of the offending bar is removed.

Bottini's Galvanocaustic Prostatotomy.—Bottini, of Padula, in 1874 suggested cauterizing the prostate by means of a special instrument. He sought to burn away a portion of the gland in hope that the contraction of the scar would cause the remainder of the gland to shrink. The instrument of Bottini is shaped like a catheter, and carries a platinum blade which is heated by an electric current. Bottini's early instrument was not satisfactory and the operation never became popular until Freudenberg improved the tools in 1897 (Fig. 935).

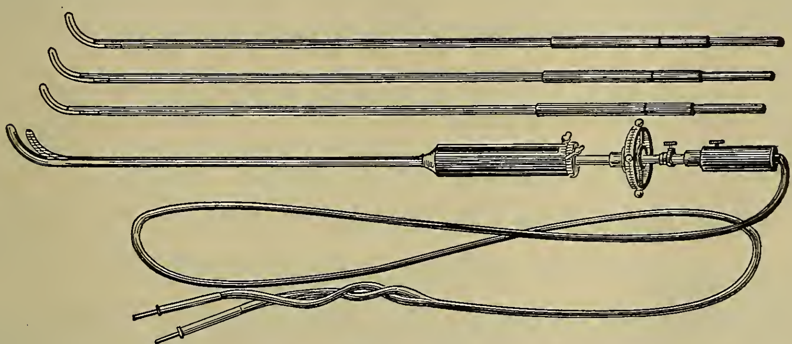

Fig. 935.—Young's modification of Freudenberg's instrument for prostatotomy by galvanocautery.

Bottini's galvanocaustic operation is performed as follows: The bladder should be emptied, irrigated, and distended with air, and the posterior urethra must be anesthetized by instillation of cocain or eucain. The current is tried to see how many seconds it requires to heat the blade sufficiently. The current is broken, the instrument is introduced, the cooling current is set in motion, and one assistant watches this and nothing else. The current is turned on and the surgeon waits the required number of seconds for the blade to become red hot (twelve to fifteen seconds), and then turns the screw at the handle, and burns a groove in the prostate. A groove should be burned toward the rectum, one to the side, and, if it is thought desirable, one to the opposite side. No groove should be burned toward the pubes. When a groove has been burned, the blade is returned into its sheath, the current being increased while doing so in order to keep the blade from adhering to the tissue, then the current is shut off. After withdrawing the instrument it is not necessary to introduce and retain a catheter. The patient is confined to bed only twenty-four hours, there is rarely bleeding or fever, and the results are fairly good. The scars contract and the gland atrophies. During the period of healing a steel sound should be passed from time to time (Bangs). It is alleged that fibrous stricture of the neck of the bladder may follow in some cases.[1]

[1] For description of this operation see Freudenberg, in "Berliner klin. Woch.," No. 46, 1897; and Willy Meyer, in "Med. Record" of March 5, 1898, and May 12, 1900.

Bottini's operation is the procedure to be selected for a sclerotic prostate and for hypertrophy in a feeble and aged individual with damaged kidneys. It is not probable that the cautery operation will ever replace prostatectomy. The best instrument is Young's modification of Freudenberg's instrument (Fig.

Fig. 936.—Incisions of the middle lobe (Young).

935). Figures 936 and 937 show various methods of making the cuts as advised by Hugh H. Young. When there is a distinct and pedunculated median lobe the ordinary plan of burning fails entirely; but, as Young shows (Figs. 936, 938), if an oblique cut is made on each side across the base, this lobe will drop

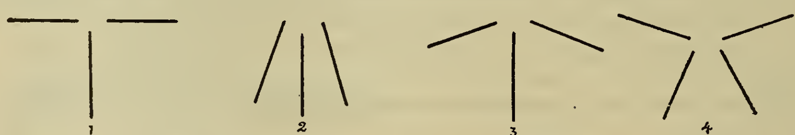

Fig. 937.—Different incisions of prostate gland in Bottini's operation (after Young).

out of the way and quickly atrophy. Bottini's operation does not gain in public confidence.

Castration and Vasectomy.—In 1886 Sanitzin demonstrated clinically the shrinking of a large prostate after double castration (Hawley, in "Annals of Surgery," Nov., 1903). In 1893 Ramm, of Norway, performed double castration in order to cause shrinking of an enlarged prostate. In 1893, after a long series of careful experiments, J. William White recommended the operation of bilateral orchidectomy for the treatment of prostatic hypertrophy. He proved that removal of the testicles causes a rapid shrinking in an enlarged prostate. Much of this shrinking may be due to diminution of congestion and edema, but true atrophy undoubtedly occurs in the glandular elements. Very remarkable results have been recorded. In some cases the patients become absolutely comfortable and dispense entirely with the catheter. Cystitis ceases, and desire to urinate frequently becomes less marked. Unilateral orchidectomy has been employed, but it is not satisfactory. In 1894 Mears suggested ligation of the spermatic cord. In 1895 Lauenstein suggested division of the spermatic cord. In 1896 Tilden Brown suggested ligation of the

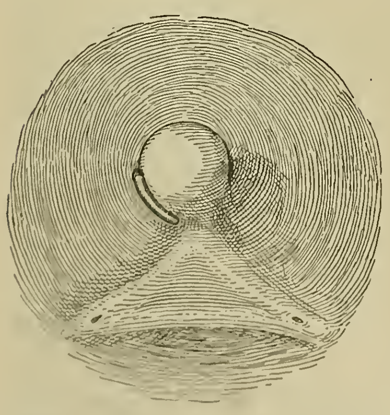

Fig. 938.—Incising the middle lobe (Young).

vas. Reginald Harrison in 1896 advised section of the vas. Lennander in 1897 proposed exsection of the vas deferens (*vasectomy*). It is slower in its results, but just as certain as castration. In spite of the great simplicity of orchidectomy the mortality has been considerable (from 11 to 18 per cent., according to some authors. Socin and Burckhardt say 16.2 per cent.). In several instances mental disturbance has followed the operation. Castration is now very seldom performed, as vasectomy is just as useful and is safer. Vasectomy is valueless in cases of fibroid prostate, does some good in adenoma, but is most valuable when the prostate is generally hypertrophied and prone to great congestion, causing violent symptoms. The testicle does not atrophy after vasectomy, mental disturbance does not occur because the internal secretion of the testicle is still furnished to the organism, and impotence may not develop, though sterility must.

Other Methods.—Among other operations which have been suggested are: ligation of the vascular elements of the cord; resection of all the cord elements except the vas and its artery and vein (*angioneurectomy*, proposed by Albarran in 1897); parenchymatous injections of cocain into the testicles; and ligation of both internal iliac arteries. Angioneurectomy has a mortality of 5.5 per cent. (Socin and Burckhardt).

Selection of Operation and Results.—The relative merits of these various operations alluded to above are in dispute. It is certain that many cases of prostatic hypertrophy can be kept comfortable by aseptic catheterism. If this procedure fails, or for other reasons must be abandoned, or if the surgeon decides not to employ it, a careful study of the case should be made before selecting a special operation. The Bottini operation for a time had somewhat extensive use. Some applied it to almost any sort of case, claiming that the operation is practically free from danger. Meyer used it for any case of uncomplicated hypertrophy, but if the prostate was very large, ligated the vasa deferentia some weeks before cauterizing the prostate, in order to lessen the danger of thromboses.

A more conservative view is that of Eugene Fuller, who doubts the permanence of the results of the Bottini operation, fears that stenosis of the vesical neck may follow, and would restrict the operation to uncomplicated cases not of a grave character, and in which the bladder has not been seriously damaged. It is the operation of choice if the prostate is fibrous. It is the preferable operation if the patient is old, debilitated, or the victim of kidney disease. Some residual urine usually remains after a Bottini operation. In over 10 per cent. of cases no benefit follows. Vasectomy is used for an engorged and generally enlarged prostate. It may do great good or may fail completely. If the urine is extremely foul, some operation permitting drainage is advisable. In an adenomatous prostate in which enucleation is easy we should prefer the perineal method. In other cases in which it is probable enucleation will be hard; in cases of uncertain diagnosis; in cases in which a calculus may exist; and in cases in which the middle lobe is at fault, do a suprapubic operation, although sometimes a perineal incision may be made, and a cut be made in the prostate to bring the floor of the urethra level with the trigone.

In old men with great obstruction and with serious disease of the bladder and involvement of the kidneys, and in individuals with prostatic cancer, permanent suprapubic drainage is sometimes the most useful procedure.

The mortality from Bottini's operation is over 5 per cent. Young had 3 deaths in 41 operations.

Vasectomy done early gives a mortality of from 3 to 5 per cent. If performed later, the mortality is 10 to 15 per cent. Socin and Burckhardt estimate the mortality of bilateral vasectomy as 8.3 per cent. The mortality of bilateral orchidectomy is 16.2 per cent.

The mortality of perineal and suprapubic prostatectomy has been considered on page 1382.

Malignant Disease of the Prostate Gland.—Primary malignant growths of the prostate are not infrequently encountered, but secondary growths are much more rare than primary growths. When malignant disease does occur, it is usually cancerous. Secondary cancer of the prostate finds its most usual antecedent in cancer of the rectum. Epithelioma does not occur. Scirrhus occasionally occurs; but the most frequent form is encephaloid. Sarcoma is rare, although probably not quite so rare as has been thought. Some cases of prostatic tumor obviously inoperable when first seen by the surgeon are probably sarcomatous. Round-celled, spindle-celled, or mixed-celled sarcoma may develop. Powers says there have been but 31 authenticated cases of primary sarcoma reported ("Annals of Surgery," Jan., 1908). According to Gibson ("Jour. Amer. Med. Assoc.," April 23, 1910) there are on record 36 absolutely authenticated cases of sarcoma of the prostate. Sarcoma is most frequent in childhood. It grows rapidly, is usually soft, and causes pain in the rectum and perineum or pubic region, but early in the case, at least, there is seldom residual urine (Powers, Loc. cit.). No real cure of sarcoma has yet been reported.

Carcinoma of the prostate may occur at an earlier age than ordinary hypertrophy of the prostate. The latter does not become evident until after the age of fifty; but carcinoma of the prostate may begin at any time after the age of forty, and sarcoma of the prostate may commence in early youth.

At first the carcinomatous growth enlarges slowly; but it soon begins to grow with rapidity. It breaks through the capsule and fungates into the bladder or into the urethra. The pelvic, the inguinal, and the femoral glands become involved early in the course of the disease. It is unusual to find great obstruction to urination or to the passage of a catheter at an early period, but later both these conditions are noted. Early in the case there is pain only when obstruction to urination occurs; later, the pain in the neck of the bladder may be severe, and there may also be pain in the loin and in the sciatic nerves. Hemorrhage usually occurs. In the beginning the hemorrhage is trivial and intermittent, but when fungation exists, large hemorrhages generally take place. The blood is usually mixed with urine, but there is sometimes a large hemorrhage unassociated with micturition. The urine is not likely to contain pus or any large quantity of mucus unless the bladder is involved in the growth.

When the prostate gland is felt by means of a finger in the patient's rectum, it is found to be of stony hardness and to be firmly anchored in place. Reginald Harrison points out that an ordinary hypertrophied gland is not so firmly anchored as a carcinomatous gland; that the bowel moves over it with freedom; and that, although it is firm to the touch, it is not of stony hardness. The patient with carcinoma of the prostate loses flesh rapidly and develops distinct cachexia, and metastatic deposits are likely to form in the vertebral column, in the kidneys, and in other organs and structures.

In making a diagnosis Harrison insists upon the value of the cystoscope. He says that in cancer one does not find much intravesical projection, and that what projection there is is uneven and irregular. In an ordinary adenomatous prostate, on the contrary, the surface is smooth and rounded and projects into the bladder.

Treatment.—Radical operation is out of the question in these cases. Permanent suprapubic drainage is made in most instances, and usually gives the patient great relief. (See "Remarks on Cancer of the Prostate," by Reginald Harrison, in "Brit. Med. Jour.," July 4, 1903.)

Tuberculosis of the prostate gland is rarely primary. It is usually secondary to tuberculosis of the kidney. It may follow tuberculosis of the epididymis. In the majority of cases of tuberculosis of the prostate the lungs are involved in a tuberculous process when the patient is first seen by the surgeon. The disease appears particularly between the ages of twenty and thirty years, but it may attack elderly men and even the aged. It begins by the formation of a number of tuberculous nodules in the immediate neighborhood of the prostatic tubules. These nodules caseate and run together, forming cavities and, eventually, tuberculous abscesses, which are prone to rupture into the urethra. In very rare instances a large tuberculous abscess ruptures through the perineum, into the rectum or into the peritoneum.

The disease occasionally undergoes spontaneous cure through fibrous tissue formation or calcification. The tuberculous process is liable to spread to the seminal vesicles, the bladder, the ureters, and possibly the peritoneum; and in some cases it inaugurates thrombophlebitis and pyemia.

Symptoms.—The patient suffers from pain during micturition; there is frequent micturition, and from time to time the urine contains blood. Attacks of cystitis take place, and weakness and a loss of flesh are greater than is commensurate with any ordinary inflammation. Tuberculosis of the prostate alone is said not to cause marked hectic fever, but when adjacent structures become involved the temperature is definitely elevated and becomes characteristic. When the disease has advanced there is not unusually urinary incontinence, on account of the involvement of the circular muscular fibers about the neck of the bladder. Commonly, there is a mucopurulent discharge, or mucopurulent matter may be obtained by massaging the prostate. This matter may contain tubercle bacilli, and in some cases the urine also contains bacilli. Early in the course of the case rectal examination detects some enlargement of the gland, many nodules, and tenderness; later in the disease it finds marked enlargement and areas of softening.

Treatment.—Early in the case Senn recommends parenchymatous injections of iodoform emulsion, the punctures being made through the perineum. If these fail, operation must be considered. When one takes into account how rare primary tuberculosis of the prostate is, one is impressed with the infrequency with which a radical operation should be attempted. If there is absolutely no evidence that any adjacent organ is involved or that any distant focus of disease exists, it is justifiable to perform perineal prostatectomy. As a rule, however, the only surgical operation performed consists in making a curvilinear incision in front of the rectum, which exposes the prostate, and permits the surgeon to open and curet caseous foci. If an abscess forms, it should be evacuated by means of a perineal incision and cavities should be curetted and packed with iodoform gauze.

When a patient is convalescent after an operation or if it is determined that no operation is advisable, full antituberculous treatment is employed (see page 230). One should look to the patient's general health, administer urotropin, and avoid using instruments as much as possible; because, as Sir Henry Thompson has shown, instrumentation irritates the prostate, causes a great deal of pain, and makes the disease worse in every case.

Retained and Malplaced Testicle.—The normally descended testicle is entirely within the scrotum. In 1 person of 1000 there is either undescended or ectopic testis. In 80 per cent. of individuals the testicles have descended at birth; most often it is the right testicle which fails to descend. Sometimes a testicle descends after being retained for months or even years. In Keyes's case it descended in the thirtieth year. Late descent usually causes hernia, and in 90 per cent. of all cases hernia exists. The testicle may be arrested in its passage to the scrotum (*cryptorchism*, single or double); it may remain in

the lumbar region; it may reach the internal abdominal ring; it may lodge in the inguinal canal; it may emerge from the external ring, but fail to enter the scrotum; or it may pass into an unnatural position, as into the perineum or the crural canal (*ectopia of the testis*). The failure of descent may be unilateral or bilateral, but when bilateral the degree of descent is seldom the same on the two sides. The gland may be, but seldom is, functionally active. When retained in the abdomen it never has the power of spermatogenesis. Before puberty the testicle is usually normal, but after puberty there is practically always more or less atrophy. In about 1 case out of 5 there is spermatogenesis for a time. A retained testicle is liable to attacks of orchitis and may become tuberculous, carcinomatous, endotheliomatous, or sarcomatous. In most cases there is neither pain nor tenderness, and the patient presents himself for treatment because a lump has appeared in the groin. In some cases there are sudden attacks of violent pain, accompanied by nausea (Rawling, on "Incompletely Descended Testicle," in "Practitioner," August, 1908). A testicle in the inguinal or crural canal or in the perineum is far more apt to become sarcomatous than one retained within the abdomen. Over 10 per cent. of cases of sarcoma of the testicle are in undescended glands. Russell Howard ("Practitioner," Dec., 1907), out of 57 cases of undescended testicle, found 15.7 per cent. with malignant disease. In double cryptorchism, in which the testicular function has been abolished, there is delayed union of the bony epiphyses and epiphyseal fractures are common, and there may be excessive growth of long bones. The same liability is noted in those subjected to castration in infancy. When such a subject reaches manhood, he may develop some disease of the skeleton which is usually seen only in children (Gross and Sencert, "Rev. de Chir.," No. 11, 1905). In operating on these cases we usually find a well-developed gubernaculum and a vaginal tunic extending below the testicle.

Treatment.—If one testicle is undescended at or after the eighth year of life and before puberty, if it lies in the canal, and if the other testicle is sound, the former should be removed if it is found impossible to draw the gland into the scrotum. Both testicles should not be removed from a child: one should be placed within the abdomen. I would save one testicle in order to have the child certainly enter and remain in the masculine groove. Removal of both testicles is permissible in an adult, because he has definitely become and will remain masculine, and undescended or ectopic testicles in an adult are or will surely become functionally useless and menaces. If a testicle is retained in the abdomen it should not be operated upon unless it causes trouble. Always try to get a retained gland into the scrotum before the age of puberty. If it is retained after puberty, it will be almost certain to be or to become functionally useless. An ectopic testicle should be restored to the scrotum if possible; if not, it should be removed. Even when operation is performed to replace the testicle, success is seldom enduring. In Rawling's 29 cases only 4 were permanently successful. Other operators, however, claim better results. For instance, Broca reports 79 cases traced from one to six years, and in 31 of them the result was perfect and permanent. The method I employ is that advocated by Coley, viz., Bassini's incision through the aponeurosis, separation of the cord from the peritoneum (it is usually in the posterior sac wall); removal of the vaginal process, the cremaster and fibrous adhesions around the cord; the making of a scrotal pouch by the fingers, closure of the canal as in hernia; suturing of the cord to the pillars of the external ring, as advocated by Dowd. This is practically Broca's method. Bevan operates for a testicle within the canal by separating and dividing the vaginal process, removing all the coverings of the cord, and leaving the testicle suspended by the vas and spermatic vessels only. This proceeding gives the testicle a very wide range of mobility. A pocket is made in the scrotum by

means of the finger, the testicle is placed in the pocket, and remains there without suturing. The canal is now sutured as in a Bassini operation without cord transplantation. There is a certain though small risk of gangrene of the testicle after Bevan's operation. I believe Bevan's method should be employed in the more severe cases. If there is no hernia, operation should not be performed until between the eighth and twelfth years of life.

Orchitis is inflammation of the testicle. *Acute orchitis* may follow cold, wet, traumatism or epididymitis, and may follow or develop during gout, mumps, rheumatism, or a specific fever. The testicle is round, swollen, tender, and very painful, the scrotum is red and swollen, the tunica vaginalis is filled with fluid, and there is fever. *Chronic orchitis* results from the acute form or from a chronic urethral inflammation, and is almost always combined with epididymitis. *Gonorrheal orchitis* is rare and almost certainly results in sloughing of the testicle.

The **treatment** of the *acute* form consists of rest in bed and applications as for epididymitis (see page 1397). The *chronic* form requires the removal of the causative lesion, if possible, the wearing of a suspensory bandage, applications of ichthyol or mercurial ointment, and the administration of iodid of potassium by the mouth. Strapping with zinc oxid adhesive plaster may do good. Castration may be required.

Tuberculosis of the testicle may perhaps be primary, but in the vast majority of cases is secondary to tuberculosis of the kidney, prostate, bladder, or seminal vesicles. As Keyes ("Annals of Surgery," June, 1907) says, careful examination will show one of three conditions—tubercle bacilli in urine, indurations in the prostate, and vesicles or "a distinct haze in the urine due to prostatic catarrh." Tuberculosis of the prostate or vesicles exists in probably one-half the cases (Barney, in "Boston Med. and Surg. Jour.," March 14, 1912). In about one-third of the cases there is evidence of tuberculosis distant from the genito-urinary organs (especially in the lungs or bones). Patients with tuberculosis of the testicle are nearly always sterile. The disease may be preceded by pulmonary tuberculosis, lymphatic tuberculosis, peritoneal tuberculosis, anal fistula, renal tuberculosis, or tuberculous disease of bones or joints; and primary tuberculosis of the testicle may be followed by near or distant tuberculous lesions. In some cases involvement of the prostate exists, but cannot be detected (*latent tuberculosis of the prostate*); in other cases the prostate is in a state of subacute inflammation. The epididymis is usually involved before the testicle and early chronic lesions are localized there for some time. In most cases the bacilli reach the prostate and vesicles by way of the blood, and reach the epididymis by way of the vas deferens, the lesions of the prostate and vesicles developing first or remaining latent. In some cases tuberculosis of the kidney or bladder is followed by tuberculosis of the testicle. The spread from the prostate, vas, or bladder is by epithelial infection. There is no evidence confirmatory of the idea of ascending infection from the urethra. In a child with an open vaginal process, tuberculous peritonitis may directly cause tuberculous epididymitis. The disease begins in one testicle, but in the vast majority of cases the other testicle becomes involved after a few weeks or months. If the other testicle remains free for three years its chance of remaining free is good. If but one epididymis is involved the testicle may not be affected for weeks or months. Von Bruns says that in 18 per cent. of such cases the testicle is not involved for six months; in 40 per cent., for over two months ("Archiv. f. klin. Chir.," Bd. 63, H. 4). It usually comes on gradually, but it may begin acutely, as I have seen in two instances during the progress of tuberculous peritonitis. An acute onset or an acute exacerbation of a chronic case usually means mixed infection. The disease may follow a slight injury or inflammation, and is most common in young men, but may arise at

any age. The causal influence of antecedent or existing gonorrhea is doubtful. Some maintain that sexual excess predisposes. There is often a family history of tuberculosis. A chronic case begins by swelling of the epididymis. Palpation detects one or two or several rounded nodules, or a diffuse hardening. In the latter case the epididymis is much enlarged, and there is usually a slight hydrocele. Rectal examination commonly detects nodules in the prostate and vesicles. In a few cases there are frequency of micturition, tenesmus, hematuria, and seropurulent fluid can he massaged from the vesicles and prostate and milked from the urethra. In some cases bacilli are found in the urine. In others the urine is hazy. In about 80 per cent. of cases the guinea-pig test will prove the presence of bacilli. In some cases the urine is normal. Sooner or later nodules appear in the testicle. The vas is always swollen and may or may not be palpable. In an acute case one testicle is involved. The testicle is very painful and the epididymis is greatly swollen and smooth. The testicle quickly swells, there is always a hydrocele, and the scrotal skin becomes

Fig. 939.—Obstructive hyperemia for the testicles. The ends of the elastic tube are held by the patient, crossed. A piece of tape is placed beneath to be tied by an attendant (Meyer and Schmieden).

reddened. In a few days the acuteness of the symptoms subsides, but suppuration occurs soon. In any case of tuberculosis of the testicle nodules tend to soften and run together. After a time the skin may become red and adherent, give way, and expose a caseous breaking-down epididymis or testicle. Caseation can occur without mixed infection, but in many cases in which softening and sinus formation occur there is mixed infection. The duration of the disease is uncertain; 10 per cent. of the 100 cases carefully studied by Keyes were known to be alive ten years after the beginning of the trouble, and 4 (and not one of them had been operated upon) seemed free from tuberculous lesions anywhere. One-third of the cases that suppurated were apparently well after three years ("Annals of Surgery," June, 1907). Except in the acute cases the testicle is only slightly, if at all, painful, and tenderness is trivial. In one-sixth of the cases a small hydrocele forms. If a hydrocele exists the fluid should be withdrawn by tapping in order that cultures may be made from it.

Treatment.—Before attempting any operation try Bier's method. The

patient is placed recumbent, the diseased testicle is lifted upward, cotton batting is placed around the neck of the scrotum, and a rubber drainage-tube of a caliber of 25 of the French scale is wound twice around and fastened with a string or clamp. If both testicles are diseased, both are held up and the neck of the scrotum is embraced by the tube with the required firmness (see Fig. 939). The treatment is applied for two or three hours a day or longer. The patient had best be recumbent during the application. In the intervals he wears a suspensory and gets about. During the use of Bier's method full antituberculous treatment is required (see page 230). If a cold abscess forms, open it and dress the part antiseptically. If Bier's treatment fails, consider the advisability of operation. An acute case requires unilateral castration. If, in a chronic case the disease is limited to the epididymis or to the epididymis and vas, resect the epididymis (*epididymectomy*) and the vas deferens. If the testicle is diseased, *orchidectomy* is performed. It was long believed that orchidectomy was useless if the vesicles and prostate were involved, but Koenig and others maintain that vesicular and prostatic tuberculosis improves after removing the diseased testicle or epididymis. If the epididymis of each testicle is involved, bilateral epididymectomy should be performed. When both testicles are diseased and other organs and structures are not extensively involved, bilateral orchidectomy is performed or, better, the testicle which is most diseased is removed and the *diseased portion* of the other is extirpated. Cumston points out that when the testicle is diseased the disease may not be detectable even on operative exposure. Hence in doing epididymectomy he splits open the testicle to see if it is diseased. If it is not diseased he sutures it with catgut and removes the epididymis. If it is diseased he considers the advisability of unilateral orchidectomy (Charles Greene Cumston, in "Annals of Surgery," June, 1909).

In many cases after epididymectomy sinuses form. They may remain open for months. In association with and after operation employ antituberculous remedies, order a nourishing diet, send the patient to a good climate, and insist on an open-air life. Tuberculin may prove useful. A considerable percentage of unilateral cases are cured by operation (over 40 per cent.). Some few bilateral cases are cured.

Cysts and Tumors of the Testicle.—Innocent tumors are very rare; in fact, some dispute their existence. The elements of a testicular growth are very complex. A majority of growths are unquestionably malignant. Some are wholly malignant. Many show a mingling of benign and malignant elements. Even growths which are not malignant in the beginning have an irresistible tendency to become so. It is believed by many surgeons that fibroma and adenoma can arise and perhaps remain for some time benign. Embryomata are at first benign, but tend, perhaps after years, to become malignant.

Embryomata.—H. Morriston Davies ("Lancet," Feb. 17, 1912) considers embryomata to be "composite tumors containing elements derived from epiblast, mesoblast, and hypoblast." They are "developed in the body of the testicle" and not in the epididymis, though that structure may eventually be involved. Early in their development these growths are benign, but any or all the layers may become malignant (Nicholson, in "Guy's Hospital Reports," vol. lxi, 1907).

When two or more layers become malignant "a mixed tumor is the result; when hypoblast alone, the tumor assumes the character of a columnar-celled carcinoma; when mesoblast alone, of a sarcoma or myxosarcoma" (Davies, Loc. cit.). When a dermoid-like growth from the epiblast becomes malignant it resembles chorionepithelioma. Nicholson (Loc. cit.) divides embryomata into solid embryomata (which often contain cysts and are common) and cystic embryomata or dermoids (which are very rare). Many surgeons regard

sarcoma, others carcinoma, as the commonest form of malignant disease. Endothelioma may occur.

Malignant Disease of the Testicle.—It may arise from an embryoma or may be malignant from the start. If a tumor which has long existed, perhaps years, begins to grow rapidly, we may assume that there is malignant change in an embryoma. It is seldom possible to diagnosticate the form of a malignant tumor. Sarcoma is usually of the small round-celled variety (the type known as lymphosarcoma). The other testicle soon becomes involved in malignancy. The growths disseminate rapidly. In 10 per cent. of cases the testicle is undescended. Any sarcoma is liable to sudden increase in size because of hemorrhage.

Nicholson ("Guy's Hospital Reports," vol. lxi, 1907) divides carcinomata into encephaloid (which is commonest) and scirrhus (which is rare), and regards so-called columnar carcinomata as teratomata. Davies ("Lancet," Feb. 17, 1912) admirably sums up the clinical picture of malignant disease of the testicle. I have utilized his article extensively below. The tumor may attain a great size (that of a cocoanut). It is usually oval, but may exhibit a few rounded projections "due to the presence of degeneration in the tumor or of fluid in the tunica vaginalis." Early in the development the growth is smooth (except for the projections mentioned), later it breaks through the tunica albuginea and so comes to have an irregular surface. The epididymis is at first free, but sooner or later becomes part of the tumor. The consistence of malignant tumors is very variable (may be hard, elastic, soft, or fluctuating), and the consistence of a tumor may vary in different parts. In most cases there is an associated hydrocele, in which the fluid may be limited or may be distributed throughout the entire sac. The hydrocele may be translucent, the tumor never is. Pain is seldom severe and tenderness seldom acute in the testicle. I have seen terrible agony when the lumbar glands are involved. The tumor when raised on the hand feels very heavy. The cord becomes enlarged because of involvement.

The growth finally adheres to the scrotum, and the skin reddens and gives way and fungation occurs. When this happens there is severe pain. Sarcoma of the testicle, unlike sarcoma in most other regions, causes early glandular involvement. Carcinoma, of course, involves glands. The inguinal glands are not involved unless the scrotum is attacked. The lumbar glands receive the testicular lymphatics. Secondary growths are early and widespread and are common in the skin.

H. M. Davies emphasizes the great fatality of malignant disease of the testicle; quotes Chevassu's collection of 100 cases treated by castration, of which 81 died of malignant disease and only 19 were cured, and insists that "early diagnosis and the removal of the testicle and surrounding fascia and the glands in the lumbar region offer the only hope of decreasing so appalling a mortality" ("Lancet," Feb. 17, 1912).

Orchidectomy, or Castration (*Excision of a Testicle*).—Bilateral castration should never be performed without deliberate consideration. It often produces grave mental disorder. This is in part the result of the mental depression attendant on knowing that the highly prized glands are gone for ever, and in part the loss to the organism of the internal secretion of the testicles. A boy castrated before puberty never becomes potent. A man may retain potency for a considerable time after castration. I removed a tuberculous kidney from a man who had been castrated by my colleague, Dr. Horwitz, two years before, yet he was still able to have intercourse. Unilateral orchidectomy does not make a man either sterile or impotent and does not produce mental disturbance. In orchidectomy for

benign disease an incision is made over the cord, commencing just outside the external ring and running down over the base of the tumor. Clamp the cord and divide it near the ring, remove the testicle, ligate the spermatic artery alone, and then ligate the entire thickness of the cord. The cord is ligated with chromic gut. The skin is sutured with silkworm-gut. Drainage is not required. It is often advisable to remove a considerable amount of scrotal skin. Orchidectomy for malignant disease must be a much more radical procedure. After the cord has been divided and the testicle removed, as in the ordinary operation, the incision is prolonged along and through the roof of the inguinal canal, and is continued in the same direction to a point a little above the anterior superior spine of the ilium. The incision is then curved and carried up to "the costal margin at the level of the tenth rib" (Davies, in "Lancet," Feb. 17, 1912). The peritoneum is exposed. The cord is traced well into the true pelvis, is tied, and divided. The fascia over the iliacus and psoas muscles is dissected, "together with the contained spermatic vessels and lymphatics," and the glands upon "the inferior vena cava and aorta" are removed (Davies, Ibid.). This operation was first performed by Grégoire in 1905. Davies did the thirteenth operation on record (Ibid.).

Epididymitis, or *inflammation of the epididymis*, is usually due to inflammation of the urethra. It is apt to occur in the stage of decline of a gonorrhea, and in such a case is announced by a notable diminution or a complete cessation of discharge. It may result from the passage of a urethral instrument, the voiding of urine which contains fragments of calculi, or as a complication of prostatic hypertrophy. *Acute epididymitis* is characterized by swelling of the epididymis, severe pain in the groin, and tenderness over the posterior part of the testicle. The pain becomes acute, swelling rapidly increases, and the constitution sympathizes. The swelling is due partly to engorgement of the epididymis and partly to fluid in the tunica vaginalis (*acute hydrocele*). *Chronic epididymitis* is usually linked with orchitis, and it follows an actue exacerbation of a chronic urethral inflammation.

Treatment by aseptic puncture with a tenotome, if fluctuation is marked, will relieve tension and pain. Hagner makes multiple punctures in the epididymis. Leeching over the external abdominal ring, the use of an ice-bag early in the case, elevation, application of guaiacol, and administration of laxatives and opium constitute the usual treatment in the acute stage. Applications of guaiacol over the cord, epididymis, and testicle seem to relieve pain and distinctly lessen swelling. Two applications a day should be made for one week. At each application paint the scrotum and over the external ring with 15 drops of guaiacol in 1 dram of glycerin or olive oil. Strapping is employed as the inflammation subsides. The treatment of the chronic form is the same as that for chronic orchitis.

Strangulation of the Cord by Axial Rotation.—In nearly one-half of the cases the testicle is undescended or only partly descended. In every case there is a long mesorchium, and if a normal testicle is normally placed torsion of the cord will hardly occur (Chas. L. Scudder, "Annals of Surgery," Aug., 1901). The twisting may be toward the right or toward the left. The symptoms arise suddenly, and usually during exertion. In some cases a hernia also exists. When the rotation occurs, the testicle swells, hemorrhages take place into it, and gangrene may develop. If the cord of an undescended or partially descended testicle twists, swelling and tenderness are noted in the abdomen or groin. If the swollen testicle is in the scrotum, the gland feels nodular and the epididymis is found to be anterior instead of posterior, as it is in a normally placed gland. The symptoms are sudden pain, vomiting, moderate shock, and a swelling in the groin or a swollen testicle in the scrotum. The swelling receives no impulse on coughing. The symptoms resemble those of

strangulated hernia, but are less violent, and the bowels, though often much constipated, are not obstructed.

Treatment.—An incision should be made, and if the twisting was recent and the testicle is not gangrenous, the cord may be untwisted and the testicle fastened to the scrotum by a catgut stitch. If the testicle is gangrenous it should, of course, be removed. Scudder tells us that in 88 per cent. of cases the testicle is found to be gangrenous. According to Scudder, there are 32 cases on record: 31 were operated upon and 1 was not, but all recovered; in 3 the testicle sloughed and in 2 it atrophied ("Annals of Surgery," Aug., 1901).

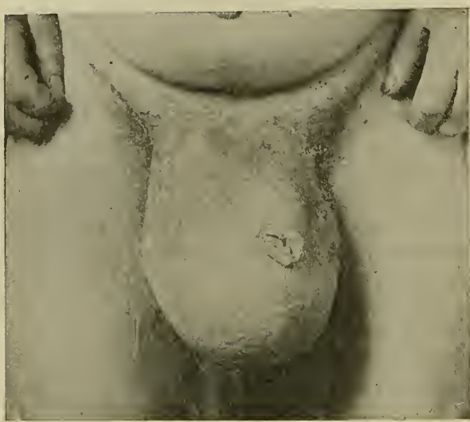

Fig. 940.—Hydrocele of tunica vaginalis (Horwitz).

Vaginal hydrocele (*chronic hydrocele*) (Figs. 940 and 942, *e*) is a collection of fluid in the tunica vaginalis testis. An enlargement of the testis may cause it (*secondary hydrocele*), but in most instances the cause is unknown and no signs of inflammation exist (*primary hydrocele*). The fluid is albuminous, but it does not coagulate spontaneously; it is thin, straw colored, and may contain crystals of cholesterin. The testicle is at the lower and back part of the sac. The pyriform mass fluctuates, is translucent, grows from below upward, and the introduction of an exploring needle permits the yellow fluid to flow out. Sometimes a hydrocele has an hour-glass shape. This is the *hydrocele "en bissac"* of the French. In this condition (Fig. 941) two cavities exist, usually but not invariably communicating. The constriction between the cavities is due to inflammatory thickening.

Fig. 941.—Hydrocele "en bissac." This hydrocele extends up the cord into the inguinal canal and to the internal abdominal ring (Horwitz).

Treatment. — In secondary hydrocele the treatment of the diseased testicle is the essential plan. We discuss here the treatment of primary hydrocele. Simply tapping the sac with a trocar is only palliative; air must run in as fluid runs out, and suppuration may occur, which will be dangerous without drainage. Never tap a rigid sac. The injection of irritants should be abandoned, as it exposes the patient to serious danger because of inflammation occurring without provision for drainage. A good plan is to incise the sac, dry its interior by bits of gauze, swab it out with pure carbolic acid, pack it with iodoform gauze, and dress it antiseptically. The packing is removed in

twenty-four hours and the wound is allowed to close. In most cases I prefer this method. If the sac is rigid and will not collapse, either stitch it to the skin and pack it or excise a large portion of its parietal layer and insert a drainage-tube (*Volkmann's operation*). Another plan is to tap the sac with a trocar and cannula, leaving the cannula in place as a drain for some days, and dressing antiseptically.

Longuet's operation is easy and is advocated by many surgeons. It is called *extraserous transposition of the testicle*. It was introduced by Longuet in 1898 ("Progrès Méd.," Sept. 21, 1901). Doyen and Winklemann do a similar operation. Jaboulay, too, advocates splitting the sac and turning it inside out. He folds it around both the testicle and cord and stitches it so that the smooth endothelial surface of the tunic will be in contact with the raw scrotal tissue. It will adhere to the scrotal tissue ("Keen's Surgery," vol. iv). A local anesthetic is injected and an incision 2 inches in length is made. The testicle is lifted from the scrotum. The serous and all the other coats except the skin fall together behind and make a sheath for the cord. One catgut suture will hold them behind the cord. A bed is made for the testicle beneath the inner edge of the skin wound by tearing with the fingers. The testicle is rotated on its long axis and inserted into this cavity. The testicle rests against the scrotal septum, and in front of the gland is the cord covered by the tunic. The skin is sutured and the wound is dressed. E. Wylly Andrews devised *the*

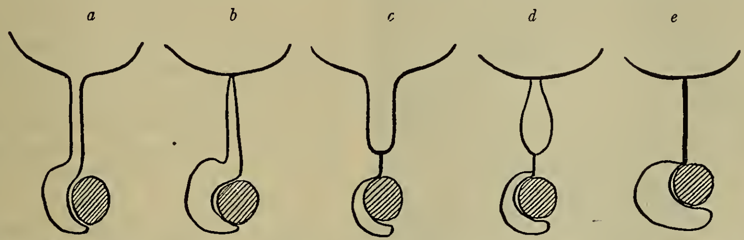

Fig. 942.—Varieties of hydrocele: *a*, Congenital; *b*, infantile; *c*, funicular; *d*, encysted; *e*, vaginal.

bottle operation ("Keen's Surgery," vol. iv). The unopened tunic (with the testicle) is separated from the scrotum and dislocated through the scrotal wound. A small incision is made near the summit of the funnel-like prolongation of the sac upon the cord. The sac empties and then resembles a bottle or bag with a small opening at the top. The testicle is squeezed through the opening. When this is done the sac is inside out and the edges of the small opening lie closely about the cord. The skin is closed without drainage. In some cases after doing any one of the operations which turn the sac inside out a large tender mass forms, composed of swollen testicle and thickened sac. I have had this experience several times. In such a case it is necessary to excise the thickened sac.

Congenital hydrocele (Fig. 942, *a*) is hydrocele through an unclosed funicular process into the tunica vaginalis. If the pelvis is raised the fluid runs back into the peritoneal cavity, from which it originally came.

The **treatment** is the application of a truss to obliterate the funicular process, and when that occurs, if the counterpart of an infantile hydrocele persists, puncture and scarification of the walls of the sac.

Infantile hydrocele (Fig. 942, *b*) is a collection of fluid in a funicular process and the tunica vaginalis, the funicular process being closed above, but not below.

The **treatment** is to puncture the sac and to scarify the sac wall with a needle.

Funicular Hydrocele (Fig. 942, *c*).—The funicular process is closed below, but is open above. Raising the pelvis causes the fluid to trickle back into the peritoneal cavity.

The **treatment** is the application of a truss.

Encysted Hydrocele of the Cord (Fig. 942, *d*).—In this variety the funicular process is obliterated above and below, but it is patent between these two points and fluid collects.

The **treatment** is the same as that for infantile hydrocele. If this fails, incise and pack.

Encysted hydrocele of the testicle and of the epididymis may occur. *Diffused hydrocele* of the cord is simply edema of the cord. *Hydrocele of a hernia* is the distention of a hernial sac by peritoneal fluid.

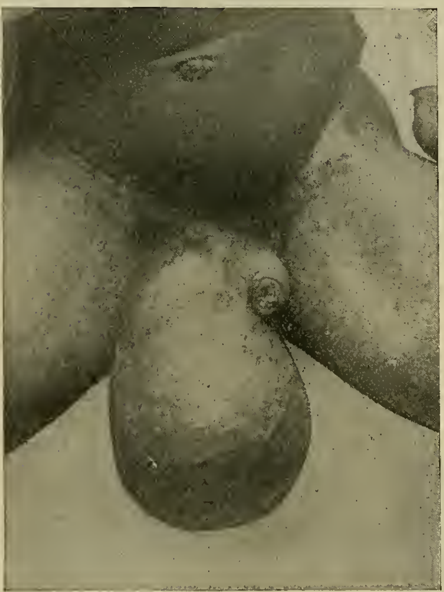

Fig. 943.—Acute hematocele of tunica vaginalis the result of traumatism (Horwitz).

Hematocele (Fig. 943).—*Vaginal hematocele* is blood in the tunica vaginalis, the result of traumatism, a tumor, or the tapping of a hydrocele. There is a pyriform swelling which fluctuates, but which gradually becomes firmer; the scrotum is livid and the testicle is below and posterior to the tumor. The *encysted* form of *hematocele of the cord* is a hydrocele of the cord into which bleeding has occurred. The *diffused* form is due to extravasation of blood into the cellular substance of the cord. *Encysted hematocele of the testicle* is due to effusion of blood into an encysted hydrocele of the testicle. *Parenchymatous hematocele* is extravasation of blood into the substance of the testicle.

The **treatment** of a recent case of vaginal hematocele is to put the patient to bed, support the scrotum, and apply an ice-bag over the testicle. If the swelling does not soon abate, incise, irrigate, and pack.

Varicocele is varicose enlargement of the veins of the venous plexus of the spermatic cord. The veins are thickened, lengthened, dilated, and convoluted. The assigned causes are straining, cough, constipation, and an occupation requiring prolonged standing. Some believe ungratified sexual desire is a cause. Hereditary predisposition is probable. There are more left-sided than right-sided varicoceles, because the right spermatic vein has valves and empties into the vena cava at an acute angle, but the left spermatic vein has no valves and empties into the left renal vein at a right angle. Varicocele is a very common condition. The elder Senn found it in 21 per cent. of 10,000 recruits. An irregular swelling exists in the scrotum and extends up the cord. This swelling feels like "a bag of earth-worms"; it exhibits a slight impulse on coughing; the scrotal skin and cremaster muscle are attenuated; the testicle lies at the bottom of the swelling and is softer and smaller than normal; the swelling diminishes on lying down and increases on standing or on making pressure over the external ring. The scrotum is pendulous and the scrotal skin frequently contains varicose veins. The testicle may be soft and shrunken. There is usually some discomfort, aching,

or dragging in the testicle and the groin, and often neuralgic pain in the cord. There may be no discomfort of any sort. A large varicocele may be free from discomfort and a small varicocele may produce much annoyance, or vice versa. There are sometimes mental depression and hypochondriasis. As a man reaches middle age a varicocele usually ceases to give trouble.

Treatment.—In treating varicocele, reassure the patient: tell him there is no real danger of impotence; order cold shower-baths, correct constipation and indigestion, give occasional tonics, and order the patient to wear a suspensory bandage. If the testicle is undergoing atrophy, if the pain and the dragging are annoying, or if the mind is much depressed, operate.

Operation for Varicocele.—Subcutaneous ligation is no longer practised. The open operation is universally employed.

The patient is placed in a recumbent position. Local anesthesia is very satisfactory. A fold of skin is pinched up over the external ring, and the surgeon transfixes it on the line of the cord, so that he will have an incision about $1\frac{1}{2}$ inches long. The skin and fascia are cut by a scalpel, the veins are well exposed, and the cord is located and held aside. A double ligature of strong catgut or chromicized gut is passed under the veins by an aneurysm needle. The threads are separated 1 inch, tied tightly, and the ends are left long. The veins between the ligatures are excised. The two gut ligatures are tied together and cut. This shortens the cord. The wound is sewed up with silkworm-gut.

Bloodgood points out that it is well to avoid dividing the genital branch of the genitocrural nerve which supplies the cremaster muscle. If this nerve should be divided, the cremaster will become lax and return of the varicocele will be favored. Bloodgood makes the incision over the external ring, draws the veins up, and resects them. A wound so placed heals more certainly and promptly than does a wound of the scrotum. Of late years I have always followed this plan.

XXXVIII. AMPUTATIONS

An amputation is the cutting off of a limb or a portion of a limb. Removal of a limb or a portion of a limb at a joint is known as "disarticulation." Amputation may be necessary because of the existence of severe injury, of gangrene, of tumor, of intractable disease of bones or joints, of ulcer which will not heal, of traumatic aneurysm, etc. A re-amputation may be required because of the existence of a defective stump or disease in the stump.

Classification.—Amputations are classified as follows: (1) As to time of operation after the injury: a *primary* amputation is performed soon after the occurrence of the accident—as soon as the sufferer reacts from shock, and before he develops fever; a *secondary* amputation is performed some time after the accident, suppuration having supervened; and an *intermediate* amputation is performed during the existence of fever, but before the development of suppuration. (2) As to the situation, where the bone is divided or according to which joint is cut through. (3) As to the form and situation of the flap.

In performing an amputation maintain rigid asepsis; completely remove the hopelessly damaged portion; sacrifice as little of the sound tissue as possible; prevent hemorrhage during the amputation, and carefully arrest it after the operation; have enough sound tissue in the flap to *cover* the bone, and enough skin to *cover* the muscles; and secure drainage at a dependent point.

Hemorrhage may be prevented by the elastic bandage of Esmarch (Fig. 944). Ordinarily we can apply this bandage from the periphery to well above the line of prospective incision, encircle the limb with an elastic band (not

the thin tube shown in the cut), and remove the bandage. The bandage and band, asepticized before using, are applied to the limb, which has been carefully sterilized. After the band has been applied the limb should not be freely or forcibly moved, because of the danger of tearing muscles which are firmly fixed by the compressing band. When elastic compression has been used in an operation the surgeon, after removal of the band, should be very careful to tie *every visible vessel.* The paralysis of the small vessels induced by pressure often prevents bleeding, and unless their mouths be found and the vessels be tied reactionary hemorrhage will occur. Reactionary hemorrhage is the great danger after the use of the Esmarch bandage, and paralysis or sloughing may also follow its employment. If there be an area of suppuration or of gangrene or an extra-osseous malignant growth, do not apply the bandage as directed above. One bandage can be applied from the periphery to near the lower border of the area of growth or infection, and another, from near the upper border of this area, up the limb. If the bandages are applied in this manner the contents of the diseased area (tumor-cells and fluid or septic prod-

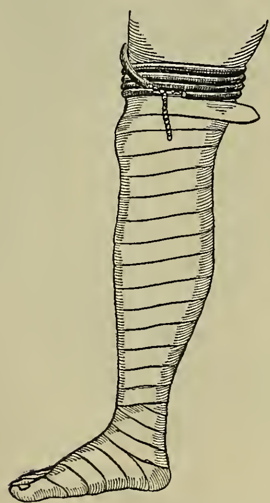

Fig. 944.—Esmarch's elastic bandage.

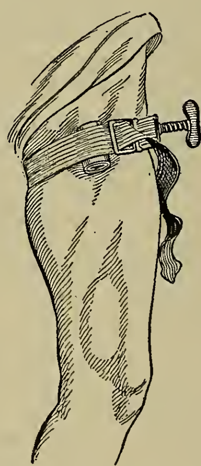

Fig. 945.—Application of tourniquet.

ucts) are not squeezed into the circulation. In cases like the above the best plan is to hold the extremity in a vertical position for five minutes, lightly stroking it toward the body with the hand, and then apply the constricting band. As a matter of fact, this plan satisfactorily empties the limb of blood, and it is not necessary in any case to force the blood out by elastic compression. Some surgeons prefer the tourniquet. Figures 946 and 947 show two forms of tourniquet. To apply Petit's tourniquet, place the plates in contact, apply a small, firm compress over the artery and a broad thick compress over the outer surface of the limb, buckle the tapes around the limb so that the plate is over the broad pad, and tighten the tourniquet by separating the plates by the screw (Fig. 945). When a tourniquet is applied to arrest bleeding during transportation, bandage the limb, sew the compress pad to a bandage, and place the plates of the instrument over the pad. Signorini's horseshoe tourniquet may be used upon the brachial artery. In hip-joint and shoulder-joint disarticulations Wyeth's pins may be passed, and after the limb is emptied of blood the band can be fastened above them. These pins prevent the band from slipping.

The instruments and appliances required for amputation are Esmarch's apparatus or tourniquet, amputating knives (Fig. 948), a bone-knife, scalpels, saws (Fig. 948), a lion-jaw forceps, bone-cutting forceps, a periosteum-elevator, retractors of linen, dissecting, hemostatic, and toothed forceps, a tenaculum, an aneurysm-needle, a probe, scissors, needles, ligatures, sutures of silkworm-gut, dressings, bandages, and solutions. A retractor has two tails for the thigh and arm and three tails for the leg and forearm: it is made by taking a piece of muslin 8 inches wide and 12 inches long and cutting tails on one side 8 inches in length.

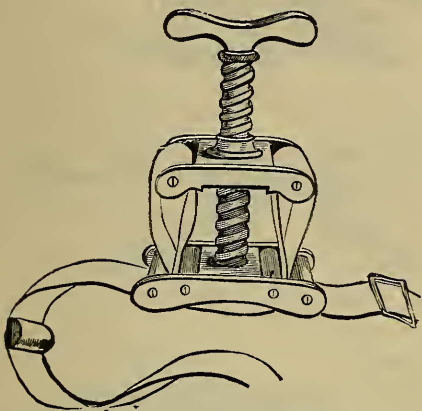

Fig. 946.—Petit's spiral tourniquet.

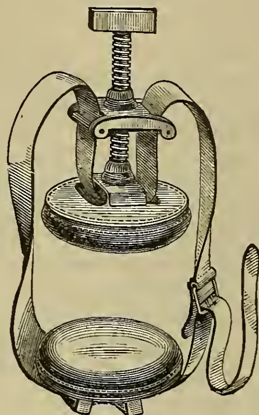

Fig. 947.—Charrière's tourniquet.

Methods of Amputating.—The *transverse circular* is the oldest method of amputating. The common circular incision is at a right angle to the axis of the limb. Kocher considers also as a circular incision an oblique cut around the limb if the line of incision "continues in one direction" (Kocher's "Text-Book of Operative Surgery," translated by Harold J. Stiles). This method is called the *oblique circular amputation.* A *racket incision* is formed by adding a longitudinal cut to a transverse circular cut. If the edges are rounded, the *lanceolate incision* is formed. *Rectangular* flaps are

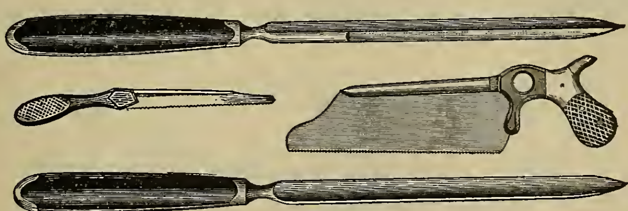

Fig. 948.—Catlin, long knife, and saws for amputation.

formed when two longitudinal incisions are added to a transverse circular cut. If the corners of a rectangular flap are trimmed, *rounded flaps* are formed. The three last-mentioned plans are considered under the head of the Modified Circular Amputation (see page 1404).

Transverse Circular Method (Figs. 949–952).—The surgeon should stand to the right of the limb and use a long amputating knife which cuts from heel to point (Fig. 949). After an assistant has retracted the skin the operator divides the soft parts by a series of circular cuts. He does not cut at once to the bone, but divides the skin and subcutaneous tissues. At the retracted edge of the

first cut the superficial muscles are divided, and after these muscles retract the deep muscles are divided. The periosteum is incised by a bone-knife and pushed up by an elevator, and after the application of the retractors the bone is then sawed, the saw starting from heel to point. A periosteal flap can be made to cover the end of the bone, but it is unnecessary. In this amputation is formed a cone whose apex is the bone and whose base is the skin edge. Figs. 950–952, from Kocher, show the steps of the operation and the shape of the resulting stump. In one form of circular amputation (*amputation a la manchette*) the retracted skin is cut by a circular sweep of the knife, a cuff of skin and subcutaneous tissue is freed and turned up, and the muscles are cut circularly at the edge of the turned-up cuff (Fig. 953). The pure circular amputation is performed on the arm and the thigh; the amputation *a la manchette* is performed chiefly through the wrist and the lower forearm.

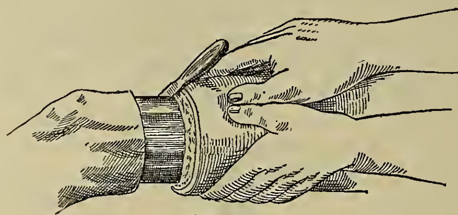

Fig. 950.

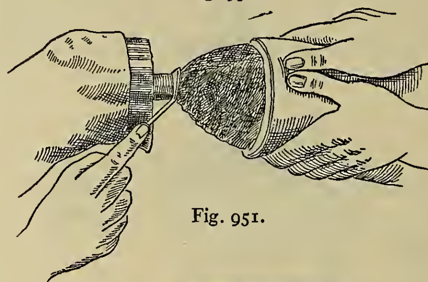

Fig. 951.

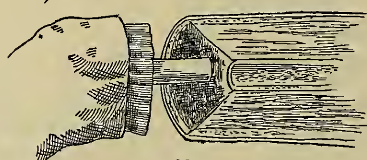

Fig. 952.

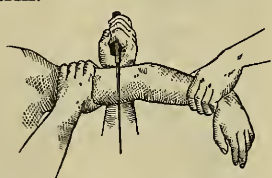

Fig. 949.—Amputation of arm by the circular method (Druitt).

Figs. 950–952.—The steps of a transverse circular amputation (Kocher).

If there is more sound skin upon one side of the extremity than upon the other, the transverse circular incision sacrifices more of the limb than is necessary and the oblique circular is preferable. An objection to the transverse

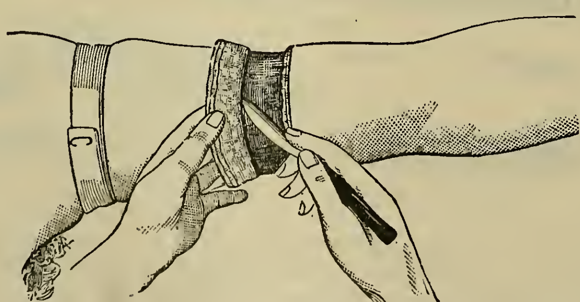

Fig. 953.—Circular amputation: Dissecting up the skin-flap (Esmarch).

circular incision is that the cicatrix lies directly at the end of the stump and is liable to cause pain when subjected to pressure.

Modified Circular Method.—In this operation the circular skin-cut may be modified by making a vertical incision to join the first wound, the muscles

being cut by a circular sweep (racket incision) or by making two vertical skin incisions (rectangular flaps). The lanceolate incision is made by round-

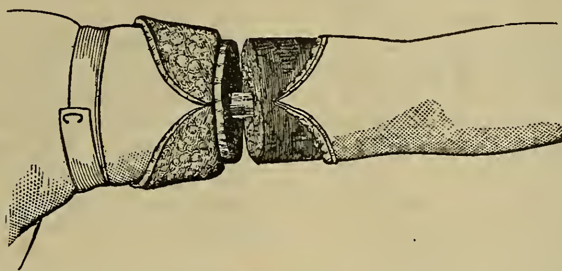

Fig. 954.—Modified circular amputation: Skin-flaps and circular cut through muscles (Esmarch).

ing the edges of the flaps which result from a racket incision. Liston's modification consists in dissecting up two short semilunar integumentary flaps and in dividing the muscles circularly (Fig. 954). This is known as the "mixed method." The modified circular method can be used upon the thigh, the leg, the arm, and the forearm.

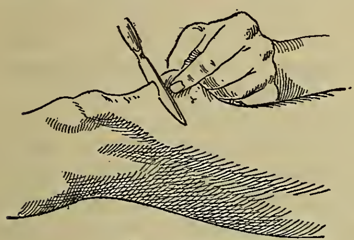

Fig. 955.

Fig. 956.

Oblique Circular Method (Elliptical Method).—Mark the upper and lower ends of the incision as shown in Figs. 955–957. The lowest incision is at a right angle to the cutaneous surface; the highest incision is parallel to the cutaneous surface (Kocher). The skin and fascia are divided so that an oblique incision to the muscles surrounds the limb. The distal elliptical portion of skin is picked up and drawn toward the body and the muscles are divided to the bone, the knife being held transversely (Figs. 955–957). Kocher points out that this flap increases in thickness

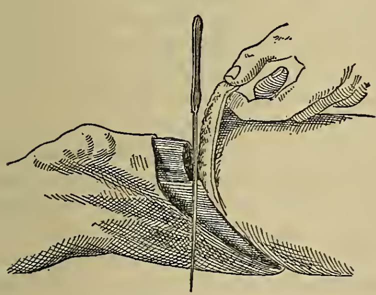

Fig. 957.

Figs. 955–957.—The early steps of an oblique circular amputation (Kocher).

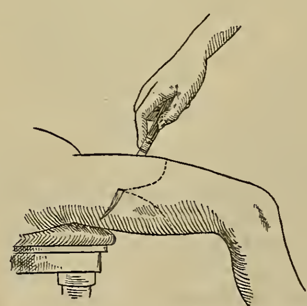

Fig. 958.—Amputation of the thigh by transfixion (Gross).

toward the bone. The rest of the muscles are divided on a level with and in the direction of the skin edge. The periosteum is cut transversely and is

treated as in the transverse circular operation. The flap of muscle and integument is brought over the wound. This method stands midway between the circular operation and the operation by a single flap, and is employed particularly in certain disarticulations.

Flap Method.—A flap may be composed of *skin* only or of both *skin* and *muscle*, but the skin-flap must always be longer than the muscle-flap, so that the latter will be covered by it. A flap containing much muscle heals badly, but the best flap has a moderate amount of muscle (enough skin to cover the muscle and enough muscle to cover the bone). Flaps may be *single* or *double*. Double flaps may be *lateral* or *anteroposterior*, *square* or *U-shaped*, *equal* or *unequal*, and they may be cut by *transfixion* (Fig. 958), by cutting from without inward, by dissection, or by cutting the skin from without inward and the muscles by transfixion.

Racket Method (if flaps are rounded, is known as the "oval" or "lanceolate" incision).—In an *oval* amputation the incision through the skin and subcutaneous tissue is an oval with a pointed end or a triangle; and the other parts down to the bone are cut from without inward. When a longitudinal incision down to the bone (see Fig. 967, *a–b*) extends from the point of the oval, the operation is called the "racket" amputation. If the longitudinal cut joins a circular cut, the operation is known as a T-amputation. The oval or racket operation is performed at the metacarpophalangeal, metatarsophalangeal, and shoulder-joints; the T-operation may be performed at the hip-joint.

Completion of An Amputation.—When an amputation has been completed, tie the main vessels, pull down the nerves and cut them high up, smooth the flaps, take off the constricting band, and after arresting hemorrhage apply sutures. In some cases the deep parts are stitched with a continusous catgut suture and the superficial parts are closed with silkworm-gut; in other cases the deep parts are not stitched at all, the skin alone being sutured with silkworm-gut. Drainage-tubes should be used except in amputations of the fingers and toes.

Special Amputations

Fingers and Hand.—In amputating the thumb and index-finger save every possible scrap of tissue. If it is necessary to amputate a finger above the middle of the middle phalanx, the attachment of the flexor tendons will be cut off and the finger will be liable to project directly backward, so that it is better either to disarticulate at the metacarpal joints or to stitch the flexor tendons to the periosteum. The flexor tendons have fibrous sheaths extending from the proximal end of the distal phalanx to the metacarpophalangeal articulations, these sheaths being thin and collapsible opposite the joints, but being thick and rigid opposite the shafts of the bone. The fibrous sheath is known as the *theca*, and when it is cut in an amputation it should be closed, otherwise it may carry infection to the palm of the hand. The theca does not exist over the distal phalanx, and it is not distinctly visible over the joint between the distal and middle phalanges. To effect closure over the shaft of a bone, strip up the periosteum and pass catgut sutures vertically through the theca and the periosteum (Treves). In amputation of the fingers and the thumb an Esmarch bandage is unnecessary, though pressure may be made upon the arteries at the wrist. Only two or three ligatures are necessary. Close with a very few sutures, so as to favor drainage between the threads.

The distal phalanx is best removed by a long palmar flap (Fig. 959, A). The plamar flap (A) is marked out by cutting through the skin and subcutaneous tissue. The incisions are next carried to the bone, the flap is dissected from the bone, the finger is strongly flexed, a transverse incision (B) is

carried across the dorsum on a level with the base of the third phalanx, the soft parts are pushed back, the joint is opened, the lateral ligaments are cut from within outward, the third phalanx is forcibly extended, and the remaining structures are cut from below upward. Fig. 960 shows the lines of the joints when the finger is flexed. The middle phalanx can be removed by the same method (Fig. 959, C). The proximal phalanx can be removed by a long palmar flap or by a long palmar and a short dorsal flap (Fig. 959, D, E).

Fig. 959.—Amputation of the finger.

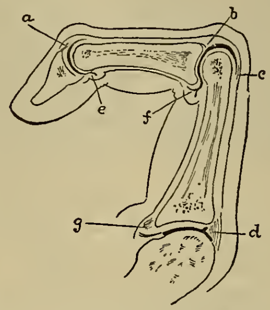

Fig. 960.—The line of the joints in the flexed position of the finger: *a*, Extensor longus digitorum; *b*, interossei and lumbricals; *c*, extensor longus digitorum and interossei; *g*, interossei and lumbricals; *f*, flexor sublimis; *e*, flexor profundus (Kocher).

Disarticulation at a metacarpophalangeal joint is best performed by the oval method. The incision upon the dorsum (A) is begun just above the head of the metacarpal bone, is carried down to beyond the base of the phalanx, and involves the skin only (Figs. 961 and 962). One incision sweeps around the finger at the level of the web, going only through the skin (B); the finger is extended and the palmar cut is carried to the bone; each lateral incision is carried to the bone while the finger is bent in the opposite direction, the flaps are dissected back to the joint, the finger is strongly extended, the joint is opened from the palmar side, and disarticulation is effected. Cutting off the head of the metacarpal bone improves the appearance of the stump, but weakens the hand, hence in a workingman it must not be done unnecessarily. If it is necessary to remove a metacarpal bone, the incision (C) is made from the carpometacarpal joint.

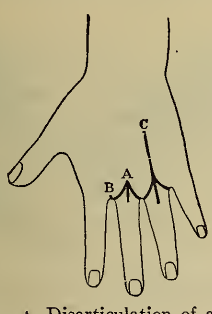

Fig. 961.—A, Disarticulation of a metacarpophalangeal joint; C, amputation of a finger with the metacarpal bone.

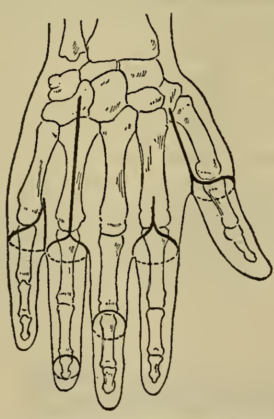

Fig. 962.—Disarticulation of the little finger and index-finger. Disarticulation of the ring finger with its metacarpal bone. Disarticulation of the thumb with its metacarpal bone (Kocher).

Amputation of the thumb through its distal or proximal phalanx is performed in the identical way employed in amputation of a finger. Amputation of the thumb, with a portion or the whole of its metacarpal bone, is performed by the oval or racket incision (Fig. 962).

Disarticulation at the wrist-joint can be done by the oblique circular method (Fig. 963) or by a double flap. In the double-flap amputation a dorsal flap is made by carrying a semilunar skin incision between the styloid processes; the skin is lifted, the wrist is forcibly flexed, the joint is opened by a transverse cut, and a long semilunar palmar flap which includes only the skin and fascia is made by dissection. Kocher prefers to amputate by an oblique incision. The lower end of this incision is about the middle of the palm and the upper end is in the line of the wrist-joint (Fig. 963). The hand is strongly flexed, the extensor tendons are divided, the posterior ligament of

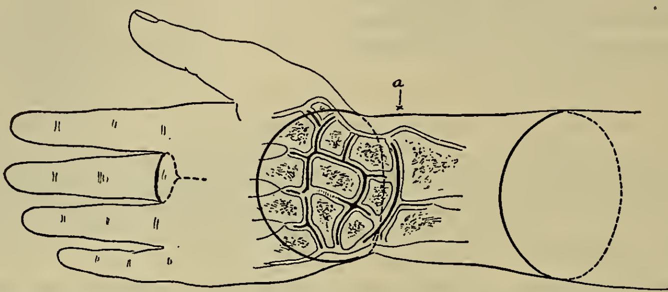

Fig. 963.—Disarticulation of the middle finger. Disarticulation at the wrist-joint. Amputation through the forearm by the oblique circular method (Kocher).

the joint is incised, and incisions below the styloid processes divide the lateral ligaments and certain tendons. The flexor tendons are separated from the bone and are divided so as to remain in the palmar flap.

Amputation through the forearm may be effected by the oblique circular method (Fig. 963), the circular, the modified circular, or the flap operation. The modified circular is an excellent plan. A semilunar dorsal skin-flap and a semilunar skin-flap on the flexor surface are made. The flaps are raised, the muscles are cut circularly (Fig. 964), the interosseous space is cleared by the knife, a three-tailed retractor is applied, the periosteum is pushed up, and the bones are sawn $\frac{1}{2}$ inch above the flap. In sawing the bones, start the saw upon the radius, draw it from heel to point, make a furrow on the radius and ulna, and saw both bones at the same time. After sawing, cut away any irregular edge

Fig. 964.—Modified circular amputation of the forearm (Bryant).

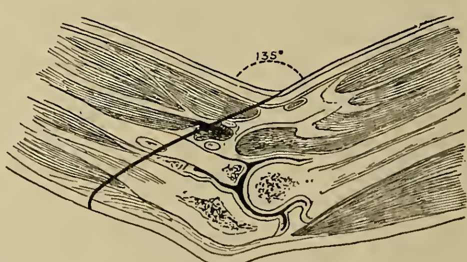

Fig. 965.—Disarticulation of the elbow-joint by the oblique circular method (Kocher).

with bone-pliers. In the lower third Teale's amputation may be done, the dorsal flap being the long one. In Teale's amputation rectangular flaps are made. The long flap is equal in width and length to one-half the circumference of the limb at the point where it is to be sawn. The short flap is equal in width to the long flap, but is only one-fourth its length. The two longitudinal cuts are at first taken only through the skin, but the two transverse cuts go at once to the bone. The flaps are dissected up from the interosseous membrane and the bone. In the middle or the upper third of a fleshy arm two semilunar

skin-flaps can be cut from without inward, and the muscles can be cut by transfixion.

Disarticulation at the elbow-joint can be done by the elliptical method or by a long anterior and short posterior flap. In Kocher's oblique operation the incision begins anteriorly over the joint-line and ends posteriorly a hand's breadth below the summit of the olecranon (Fig. 965). A posterior flap which contains the integument, the insertion of the triceps, the anconeus, and the periosteum is dissected up until the posterior surface of the humerus is reached. The joint is opened anteriorly by a transverse incision, and the radiohumeral articulation is opened from without inward (Kocher). In the double flap operation the forearm is partly flexed and a skin-cut marks out a long anterior flap, the knife being entered opposite the external condyle and being withdrawn 1 inch below the internal condyle. The muscles, which are bunched forward, are cut by transfixion. A posterior semilunar flap is made, which separates the attachments of the radius, the ulna is cleared, and the triceps is cut at its insertion (Bell). Gross advocated sawing through the olecranon and the inner trochlear surface.

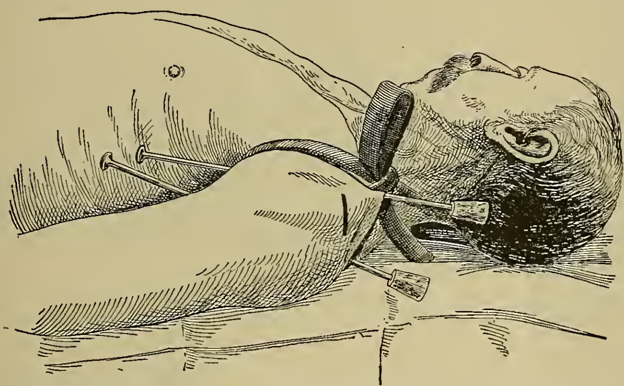

Fig. 966.—Use of Wyeth's pins in amputation at the shoulder-joint. The acromion is marked by a black line (Keen).

Amputation of the arm is best performed by marking out with a knife two equal semilunar anteroposterior flaps, the first cut being carried through the skin alone, the muscles being then transfixed with a long knife. Teale's method is shown in Figs. 438 and 439. The circular or the modified circular amputation may be performed.

Disarticulation at the Shoulder-joint.—In this operation some surgeons use Wyeth's pins to hold the Esmarch band in place. The anterior pin is entered at the middle of the lower margin of the anterior axillary fold, and emerges 1 inch within the tip of the acromion. The posterior pin is entered at a corresponding point on the posterior axillary fold, and emerges more posteriorly than the first pin and an inch within the tip of the acromion. After the extremity has been drained of blood by the Esmarch bandage or by stroking and a vertical position, the Esmarch band is applied above the pins (Fig. 966). With a competent assistant, however, the pins are not necessary, the surgeon divides his main vessels as the last step of the operation, and the assistant controls them, before they are cut and until they are tied, with his thumbs slipped back of the bone.

Larrey's Operation.—In this method of shoulder-joint disarticulation the limb is held from the side and an incision is made down to the bone, the incision beginning just below and in front of the acromion and running vertically for

4 inches down the outer surface of the arm (Fig. 967, *a–b*). From the center of this incision an oval incision (*c–d*, *c–e*) is carried around the arm, the inner aspect of the oval reaching as low as the lower end of the vertical cut. The oval incision at first involves only the skin and subcutaneous tissues. The anterior structures are divided close to the bone, and the posterior structures are next cut. To disarticulate, cut the capsule transversely upon the head of the bone; while the arm is rotated outward cut the subscapularis, and while the arm is rotated inward cut the supraspinatus and infraspinatus and the teres minor. Cut away any tissue holding the humerus to the body, hanging nerves, capsule-fragments and tissue-shreds, insert a tube, and sew up the wound vertically. Bell advises an oval incision with a racket handle. Spence used an anterior racket incision.

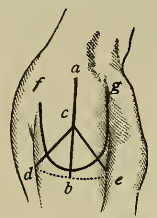

Fig. 967.—Amputation at the shoulder-joint: *a–b*, *c–d*, *c–e*, Larrey's operation; *f–g*, Dupuytren's operation.

Kocher's Operation.—Kocher makes an anterior lanceolate incision (Fig. 968). The incision begins over the clavicle just external to the coracoid process of the scapula, and is carried downward, dividing, as it advances, the anterior fibers of the deltoid muscle. "Bleeding vessels and the cephalic vein are ligatured. In the upper part of the wound the acromial branches of the acromiothoracic artery are also ligatured. The knife is carried down to the bone at the edge of the deltoid (only the upper fibers of which have been divided). The capsule is divided over the lesser tuberosity and the bicipital groove. The periosteum, the insertions of the subscapularis, pectoralis major, latissimus dorsi, and teres major are detached along with the capsule. The capsule, along with the insertions of the supraspinatus, infraspinatus, and teres minor muscles, is also detached from the upper part of the head

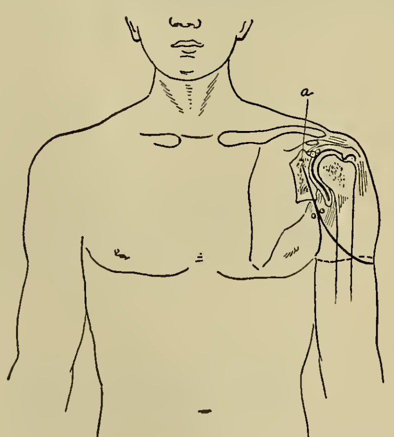

Fig. 968.—Disarticulation at the shoulder-joint by Kocher's method (Kocher).

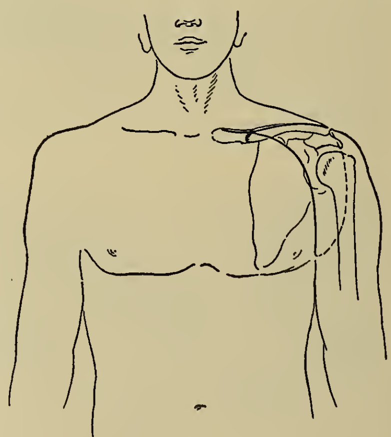

Fig. 969.—Removal of the entire upper extremity (Kocher).

and from the great tuberosity. The head of the humerus can now be protruded from the wound. In cutting down over the surgical neck it may be necessary to ligature the circumflex arteries; in any case the anterior vessel must be tied. The racket incision is now completed by dividing the skin circularly at the level of the axillary folds. The vessels and nerves are then easily isolated, the former being ligatured and the latter divided" (Kocher's "Text-Book of Operative Surgery," translated by Harold J. Stiles). Kocher

cautions us to avoid the circumflex nerve which supplies the deltoid, as the deltoid is the muscle of the stump.

Dupuytren's Operation.—In Dupuytren's shoulder-joint disarticulation a U-shaped flap is marked out by a skin-incision (Fig. 967, *f–g*). If the amputation is to be at the right shoulder, the arm is carried across the chest; the knife is entered at the root of the acromion, follows the margin of the deltoid, and is withdrawn at the coracoid process, the arm being gradually abducted and pulled off from the chest. If the left shoulder is to be amputated the procedure is reversed (Treves). The knife next cuts through the deltoid and raises a flap composed of this muscle, the shoulder-joint is exposed, and disarticulation is effected as in Larrey's method. The knife is passed down back of the bone and a short internal flap is cut.

Lisfranc's amputation is by transfixion with the formation of an anterior and a posterior flap, and can be performed very rapidly by a skilful surgeon.

Amputation of the Entire Upper Extremity.—Berger's Operation.—*The Interscapulothoracic Amputation.*—This operation, which is an amputation above the shoulder-joint, was described by Berger in 1887. By it are removed the arm, the scapula, and a portion of or the entire clavicle. It is occasionally employed in cases of malignant disease and of severe injury. The operation is attended with profuse hemorrhage, and as a preliminary the subclavian vessels should be ligated. The incisions must be varied according to the necessities of the case. In this operation Berger divides the clavicle at the junction of its outer and middle thirds, and resects the middle third of the bone; ligates and divides the subclavian vessels; cuts the anterior flap; divides the brachial plexus; marks out the posterior flap; and completes the operation by dividing the structures which hold the shoulder-blade to the chest. It is in this last step that bleeding is profuse. Figure 970 shows Berger's incisions for the operation. Figure 969 shows Kocher's incisions.

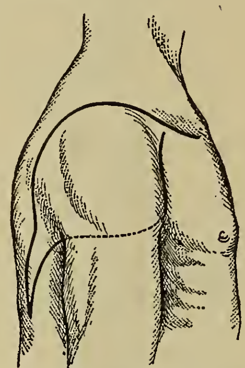

Fig. 970.—Removal of the whole upper extremity.

The usual procedure of tying the third part of the subclavian artery as a preliminary measure possesses certain disadvantages. The artery is very deeply situated at this point, is in close relation with the pleura, and is covered to a considerable extent by the vein, and the phrenic nerve is very near. Le Conte resects the entire clavicle before tying the vessels. He maintains that then one of two courses may be taken: The veins may be severed first, and afterward the artery may be exposed and tied. When this is done, the amount of blood remaining in the arm is lost. The procedure that he selects as the best, however, is to expose the axillary artery as high up as possible, and place a temporary ligature around it; then elevate the arm, empty it of blood, place a permanent ligature around the third part of the subclavian artery, and divide the artery in this portion of its course (Robert G. LeConte, "Annals of Surgery," Oct., 1902). If the scapula is involved in the tumor, the mortality is something over 23 per cent. (Berger, "Revue de Chir.," Aug., 1905). I have twice performed the operation successfully and in each case followed LeConte's plan.

Amputation of the Toes and the Foot.—Only through the great toe is *partial* amputation performed, and it is effected by the formation of a long plantar flap, just as a long palmar flap is formed from a finger. Amputation at a metatarsophalangeal joint is performed by an oval or racket incision (Fig. 971, *c*, *c*). Amputation of a toe with removal of its metatarsal bone is shown in Fig. 971, *a–b* and *d–e*.

Disarticulation at the Tarsometatarsal Articulation.—Lisfranc's Operation (*after Treves*).—In order to amputate the right foot by this method begin an incision on the outer border of the foot, behind the tubercle of the fifth metatarsal bone; carry the incision forward 1 inch and sweep it across the foot $\frac{1}{2}$ inch below the tarsometatarsal articulations; bring the incision to the inner edge of the foot, $\frac{1}{2}$ inch in front of the articulation of the tarsus with the first metatarsal bone, and carry the cut straight back along the inner margin of the foot until it reaches a point $\frac{3}{4}$ inch above the articulation of

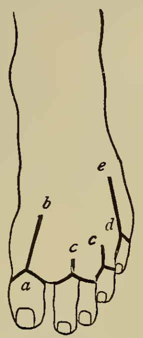

Fig. 971.—Amputation of the toes with and without the metatarsal bones.

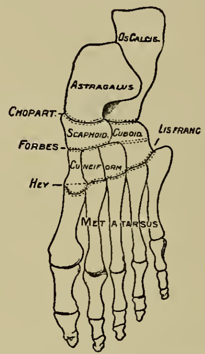

Fig. 972.—Lines in amputations of the foot (Gross).

the metatarsal bone of the great toe. A very short semilunar dorsal skin-flap is thus formed. Figure 977 shows the flaps as cut by Kocher. After the skin-flap has been dissected back for $\frac{1}{4}$ inch the tendons are divided, and the flap, which now contains all the soft parts, is dissected back to *above* the joint. A long plantar flap is cut, reaching from the origin of the first flap to the necks of the metatarsal bones. The skin-flap is dissected up until the hollow behind the heads of the metatarsal bones is reached, when, with the toes in extension, the tendons are cut across and a flap composed of all the soft parts is dissected up to above the tarsometatarsal joint. Figures 972 and 977 show the line of

Fig. 973.—Lisfranc's amputation: First step in disarticulating the second metatarsal bone (Guérin).

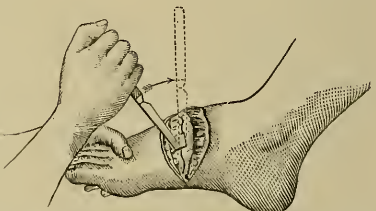

Fig. 974.—Lisfranc's amputation: Second step in disarticulating the second metatarsal bone (Guérin).

Lisfranc at the tarsometatarsal articulation. The joint is opened from the outer side according to the following rule: in separating the fifth metatarsal direct the edge of the knife toward the distal end of the first metatarsal; in separating the fourth metatarsal direct the knife toward the middle of the first metatarsal; in separating the third metatarsal carry the knife almost directly across. The separation is facilitated by bending down the front of the foot, and at the same time the tendons of the peroneus brevis and tertiûs are divided. Open the joint between the first metatarsal and the inner cuneiform

bone, turning the knife toward the middle of the shaft of the fifth metatarsal, and at the same time divide the tibialis anticus muscle. Treves says that in disarticulation of the second metatarsal the knife is to be held as a trocar, it is to be thrust between the base of the first and second metatarsal bone until the point strikes bone (Fig. 973), and is then to be raised to a perpendicular and the cut is to be made toward the external malleolus to sever the ligament of Lisfranc (Fig. 974). Divide any remaining ligaments, and also the tendon

Fig. 975.—Anterior intertarsal disarticulation (Kocher).

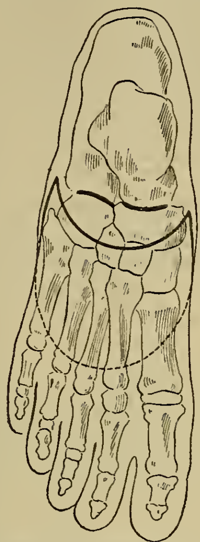

Fig. 976.—Chopart's amputation (Kocher).

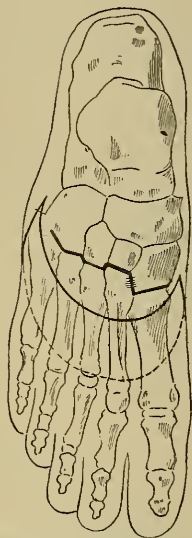

Fig. 977.—Lisfranc's amputation (Kocher).

of the peroneus longus muscle. The skin-incisions in the *left* foot are begun on the inner side, and in disarticulating the tarsal joint of the great toe is first opened. Figure 978 shows the parts after disarticulation at the line of Lisfranc.

Hey's Operation.—In Hey's method the incision is practically the same as that for Lisfranc's amputation. The four external metatarsal bones are

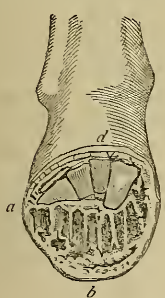

Fig. 978.—The parts after Lisfranc's amputation (Bernard and Huette).

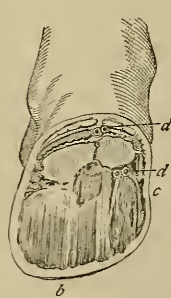

Fig. 979.—The parts after amputation by Chopart's method (Bernard and Huette).

disarticulated, but the first metatarsal is removed by sawing a portion of the internal cuneiform bone. Guérin advised sawing all the bones across. Skey advised the division of the head of the second metatarsal. Figure 972 shows the line of Hey.

Anterior Intertarsal Disarticulation (**Amputation of Forbes, of Toledo**). —The disarticulation is effected between the three cuneiform bones in front and the scaphoid behind, and the cuboid is sawn across. Figure 972 shows the line of Forbes. The incision of the soft parts is as for Lisfranc's amputation (Fig. 975).

Disarticulation Through the Middle Tarsal Joint.—Chopart's Operation (*Posterior Intertarsal Disarticulation*).—Make a transverse incision through the skin of the instep, 2 inches below the ankle-joint; cut the tendons and muscles, expose the tarsus, and make on each side a small longitudinal incision reaching to below and in front of the corresponding malleolus. The flap thus formed is retracted. The plantar flap is made as in Lisfranc's amputation. The flaps as made by Kocher are shown in Fig. 976. Open the astragaloscaphoid joint, then the calcaneocuboid joint, and disarticulate. Figures 972 and 976 show the line of Chopart. Figure 979 shows the parts after Chopart's disarticulation.

Subastragaloid Disarticulation.—A circular incision is carried around the foot at the level of the middle tarsal joint and a racket incision is added to it running below and posterior to the tip of the external malleolus (Fig. 980). "The joint between the astragalus and scaphoid is opened upon the dorsum, without opening the calcaneocuboid joint. A narrow knife is then passed backward and slightly upward beneath the head of the astragalus so as to divide the strong interosseous ligament between it and the os calcis. The soft parts are then dissected off the os calcis, first from its upper surface, then from its outer and under surfaces, and lastly from its inner and posterior surfaces. The greatest difficulty is met with at the inner side in clearing the projecting sustentaculum tali" (Kocher's "Text-Book of Operative Surgery," translated by Harold J. Stiles).

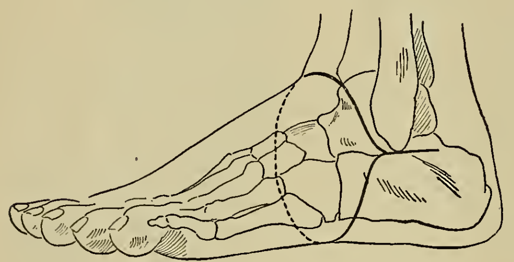

Fig. 980.—Subastragaloid disarticulation (Kocher).

Disarticulation At the Ankle-joint.—Syme's Method.—The foot is held at a right angle to the leg, and a skin-incision is carried, from just below the external malleolus, straight across or a little backward across the sole to a corresponding point on the opposite side. Do not take this incision near to the inner malleolus, as to do so will endanger the posterior tibial artery. The incision is carried to the bone, the flap being pushed back and separated from the bone by means of a strong knife and the thumb-nail until the tuberosity of the os calcis has been reached. The foot is now extended and a transverse cut is made across the dorsum, joining the two ends of the first incision; the ankle-joint is opened, the lateral ligaments are cut, disarticulation is effected, and the foot is finally completely removed by severing the tendo Achillis. A thin piece of bone including both malleoli is sawn from the tibia and fibula. The flap is perforated posteriorly to secure drainage (Fig. 438).

Pirogoff's Method.—Flex the foot to a right angle with the leg. "Make an incision from the tip of the internal malleolus across the sole, a little in front of the long axis of the tibia, to a point in front of the apex of the external malleolus down upon the bone."[1] Dissect the flap backward from the calcaneum for $\frac{1}{4}$ inch, but do not dissect the flap from the posterior portion of the

[1] "Operative Surgery," by Joseph D. Bryant.

os calcis. Join the extremities of the first incision by another cut which reaches to the bone, and which is "$\frac{1}{2}$ inch in front of the lower extremity of the tibia" (Bryant); but saw off this bony projection obliquely and leave it adherent to the tissues. The saw is used after disarticulation of the ankle-joint; it is passed behind the astragalus, cutting downward and forward, sawing the os calcis obliquely, and leaving a considerable portion in place in the flap. The lower ends of the tibia and fibula are well exposed by raising the anterior flap slightly; the sawing is begun anteriorly just above the articular surface, and is completed $\frac{1}{2}$ inch above the articular surface posteriorly. The lines *a* and *b* (Fig. 981) show the sections made by the saw. The sawn surface of the os calcis is brought into contact with the sawn surfaces of the tibia and fibula, and the flaps are sutured.

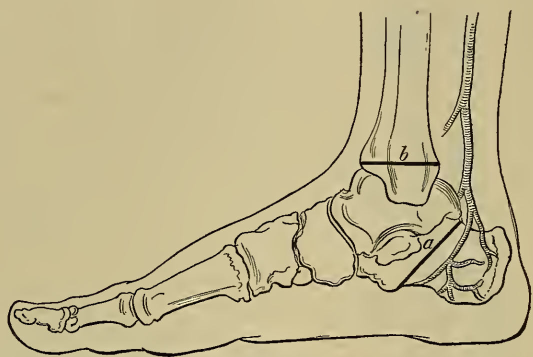

Fig. 981.—Lines of section of the os calcis and the bones of the leg in Pirogoff's amputation.

Amputations of the Leg.—The so-called "point of election" is at the upper part of the middle third of the leg. Seventy-five years ago Liston advised surgeons not to amputate in the lower third of the leg because of the scantiness of the soft parts, because the stump is apt to ulcerate, and because it is uncomfortable in an artificial leg. These views have been much modified. The amputation near the ankle is safer than the amputation near the knee, and artificial legs are now made which may be worn with comfort. In amputations of the leg by the *long anterior flap*, cut through the skin, dissect up the anterior muscles with the flap, and cut all the posterior tissues with a single transverse sweep. Amputation by the *rectangular flap*, Teale's method, is very useful (see page 1408). The long flap is anterior, and is in length and breadth equal to one-half the circumference of the limb. The short flap is one-fourth the length of the long flap. The flaps are dissected up, the bones are sawn, the long flap is turned upon itself, and its edges are sutured to the edges of the short flap.

Fig. 982.—Diagrammatic representation of amputation of the leg after the method of Bier.

Bier suggests a plan (Fig. 982) to increase the supporting power of the stump after a leg amputation. After the wound has healed, a wedge-shaped piece of bone is removed above the level of the stump. The lower extremity is turned forward and upward through an arc of 90 degrees, and unites in this position (Zuckerkandl's "Operative Surgery"). Thus the medullary cavity is closed and the skin which must bear pressure is healthy and free from cicatrices; and as the muscles are still attached to the bone, they do not undergo atrophy.

Sédillot's leg amputation (Fig. 983) is by a long external flap. A longitudinal incision is made along the inner edge of the tibia, the tissues are drawn toward the fibula, a knife is introduced and passed to the outer edge of the tibia, just touching the fibula, and is brought out posteriorly, thus transfixing the calf-muscles and cutting an external flap. A convex incision is made on

the inner side, the bones are cleared and are sawn 1 inch above the flaps, $\frac{1}{2}$ inch more being taken from the fibula than from the tibia, and the tibia being bevelled anteriorly.

Modified Circular Amputation of the Leg.—Cut semilunar skin-flaps, lay them back, and cut circularly to the bone at the edge of the turned-up flap. Another method of modified circular amputation is by adding to the circular cut a vertical incision down the front of the leg. In sawing the bones of the leg the surgeon, who stands to the outer side of the right leg or to the inner side of the left leg, divides the fibula first, and at a higher level than the tibia, and bevels the anterior surface of the tibia. In sawing the left fibula the saw points to the floor; in sawing the right fibula it points to the ceiling.

Fig. 983.—Sédillot's amputation of the leg (Wyeth).

Amputation of the Leg by a Long Posterior and a Short Anterior Flap.—In this operation a posterior U-shaped flap is made equal in length and breadth to the diameter of the limb. The skin-incision is begun 1 inch below the point where the bone is to be sawn, and behind the inner edge of the tibia, and is carried to a point posterior to the peronei muscles. The gastrocnemius muscle is divided transversely at the level of the flap, the soft parts on either side in the line of the flap being cut to the bone. Through these vertical cuts the muscles are lifted from the bones and are divided through their lower part by cutting from within outward. The anterior flap is formed by making a semilunar skin-flap and by cutting the muscles across at its retracted edge (Fig. 984).

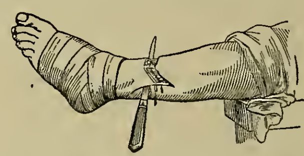

Fig. 984.—Amputation of the leg by a long posterior flap (Gross).

Amputation of the leg by lateral flaps is not a popular operation, as it offers too much encouragement to subsequent protrusion of the bone.

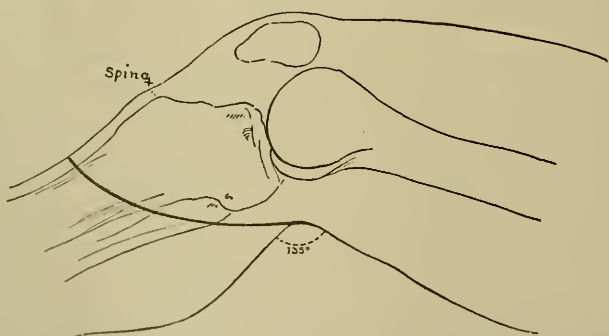

Fig. 985.—Kocher's oblique incision for disarticulation at the knee-joint (Kocher).

Amputation Just Below the Knee.—The seat of election is 1 inch below the tuberosities. No muscle is needed in the flap. Cut two flaps of skin, equal in size and of semilunar shape, these flaps beginning anteriorly 2 inches below the tuberosity of the tibia. One flap is antero-external and the other is postero-internal. The flaps are pulled up, the anterior muscles are cut as high up as possible, and the posterior muscles are cut through the middle of the portion exposed (Bell). The bone is sawn 1 inch below the tuberosity.

Disarticulation At the Knee.—In disarticulation by the long anterior flap, make a long anterior skin-flap, incise the ligament of the patella, turn up a flap containing the patella, open the joint, and complete the disarticulation by cutting from within outward and downward. The knee may be disarticulated by means of a long anterior and a short posterior flap. Kocher prefers the oblique incision (Fig. 985). This secures an anterior flap. The leg is so held that it makes an angle with the thigh of 135 degrees and "the incision falls in the continuation of the long axis of the thigh" (Kocher's "Text-book of Operative Surgery," translated by Harold J. Stiles). The posterior part of the incision is opposite the line of the joint and the anterior part of the incision ends four fingers-breadth below the tibial tubercle.

Amputation Through the Femoral Condyles.—*Syme's Method by a Long Posterior Flap.*—Carry a skin-incision, with a very slight downward curve from one condyle to the other, across the middle of the patella. Cut down to the bone, retract the flap, and cut the quadriceps above the patella. Insert a long knife at one angle of the wound, pass it back of the femur, and make it emerge at the opposite angle, cutting a posterior flap 8 inches long. Retract the posterior flap, clear for sawing, and section the condyles horizontally. Carden made a curved section of the condyles at their widest part. In children Buchanan showed that we can easily separate the lower femoral epiphysis.

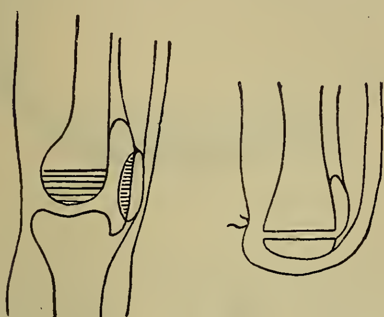

Fig. 986.—Diagrammatic representation of Gritti's operation.

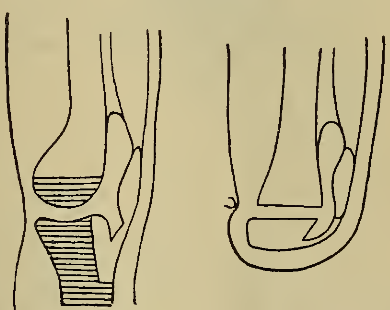

Fig. 987.—Diagrammatic representation of Sabanejeff's operation.

In *Gritti's supracondyloid amputation* an oblique incision is made. The upper end of the incision is posterior and just above the condyles. Its lower end is anterior and two fingers-breadth below the patella (Kocher). The ligament of the patella is cut, the flap is turned up, the femur is sawn at the base of the condyles, the articular face of the patella is sawn off, and the sawn patella is fastened to the sawn femur and the flaps are sutured (Fig. 986). Sabanejeff makes an anterior flap, opens the knee-joint from behind, saws the condyles at their broadest part, takes a bone-flap from the anterior portion of the tibia, and fastens it to the femur (Fig. 987).

Amputation of the Thigh.—In high amputation in the *lower third* either a flap or a circular operation may be performed. In a double-flap operation a semilunar skin-incision should be made from without inward, and the muscles should be cut by transfixion (Fig. 988). In the lower third Teale's flap or the long anterior flap may be employed. The amputation by a long anterior flap consists in making a lengthy skin-flap, reflecting it, cutting the anterior structures to the bone, again entering the long knife at one angle of the incision, pushing it back of the femur, bringing it out at the outer angle, and cutting the structures behind the bone directly backward. Bell amputates by a long anterior semilunar flap and a short posterior flap. In amputations in the *upper two-thirds* of the thigh the best plan is to mark out equal anterior and posterior

semilunar skin-flaps, divide the skin with a scalpel, enter the long knife at one angle of the anterior flap, bring it out at the other angle, and cut the muscles by transfixion. Cut the posterior flap in the same manner. Some surgeons prefer a long anterior semilunar flap and a short posterior semilunar flap. The pure circular amputation is not adapted to the thigh.

Disarticulation At the Hip-joint.—Various methods have been employed to prevent or limit hemorrhage during this formidable operation. Abernethy used digital compression of the external iliac artery or of the femoral artery. This is an extremely tiresome procedure; the finger is liable to slip; and, in any case, compression so situated fails to intercept the blood-current in a number of large vessels.

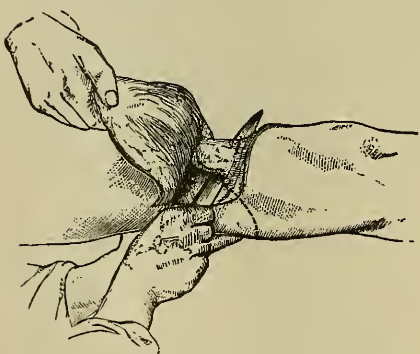

Fig. 988.—Amputation of the thigh (Bryant).

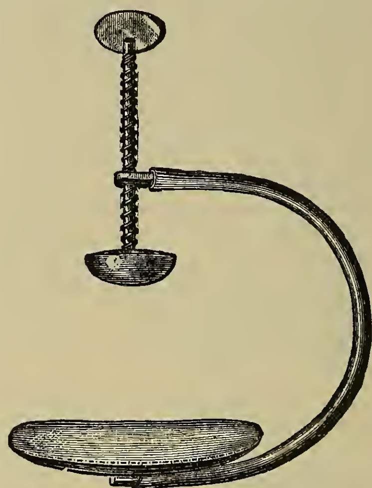

Fig. 989.—Pancoast's aorta tourniquet.

Various other methods have been employed. It was formerly the custom to compress the aorta by means of an abdominal compressor (Figs. 989, 990). A tourniquet is very likely to be displaced during the operation. The intention is to compress the artery against the spine, but in effecting this the circulation in a portion of the intestine may be impaired. In any case, as Senn says, the

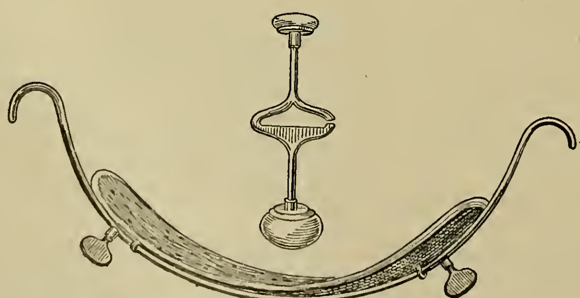

Fig. 990.—Von Esmarch's aorta tourniquet.

circulation is cut off from half the body, and the patient is exposed to grave danger from "sudden vascular engorgement of important internal organs" (Senn). Again, an abdominal compressor of this sort does not arrest venous bleeding. A number of years ago Davy suggested that a suitable cylindrical piece of wood, about 25 inches long, and shaped like a cone at the end, might be introduced into the rectum and used to compress the common iliac artery

upon the pelvic brim. This appliance is known as *Davy's lever.* It is apt to slip, and may do serious damage to the rectum.

Some surgeons have practised preliminary ligation of the common femoral artery or of the external iliac artery, and others have tied the vessels while making the flaps. I employed preliminary ligation of the common femoral with perfect satisfaction in 2 of my 4 cases of amputation at the hip-joint for sarcoma of the femur. If any form of compression is used, that recommended by Macewen, of Glasgow, is the most successful and satisfactory (Fig. 991). The weight of the assistant's body is thrown upon the patient's aorta by the right fist, placed slightly to the left of the umbilicus. McBurney has suggested the prevention of bleeding by making a small abdominal incision and having an assistant make direct digital pressure upon the iliac artery. I employed McBurney's method in one case and found it most satisfactory. In this case a sarcoma of the thigh reached up so far that no band could be applied above

Fig. 991.—Macewen's method for compression of the abdominal aorta ("American Text-Book of Surgery").

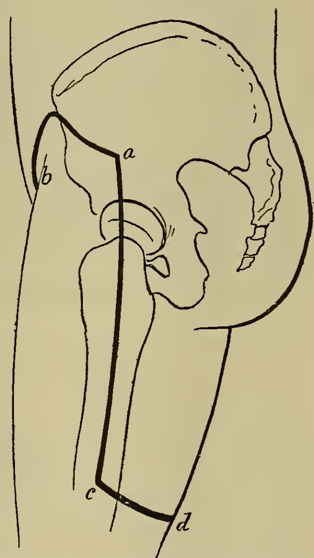

Fig. 992.—Posterior flap in author's unusual case requiring hip-joint amputation: *a–b,* The anterior incision; *a–c–d,* the external incision and the beginning of the posterior cut.

it and I was obliged to make the posterior flap shown in Fig. 992. If the constricting band of Esmarch is applied by the ordinary method, it is certain to slip. It may remain in place if applied as a figure-of-8 of the thigh and the pelvis, but even then it is uncertain.

A satisfactory method in many cases is Wyeth's, in which the constrictor is held in place by the preliminary passage of two steel pins (Fig. 993). Trendelenburg's method consisted in passing one pin and winding an elastic tube about it. Wyeth applied the principle and greatly improved the method. The outer pin is inserted $1\frac{1}{2}$ inches below and a little internal to the anterior superior spine of the ilium, and is brought out just back of the great trochanter. The inner pin is entered 1 inch below the level of the crotch and internal to the saphenous opening, and it emerges $1\frac{1}{2}$ inches in front of the tuberosity of the ischium. A sterile cork may be pushed on the end of each pin, to save the surgeon from wounding himself upon the sharp points. A cork is

apt to come off during the course of the operation. Because of the insecurity of the cork I have had made pins with removable points. After a pin has been passed, the point is unscrewed and a knob is screwed on in its place. After the limb has been emptied of blood by holding it in a vertical position for five minutes and stroking it from the periphery toward the body, the constricting band is fastened about the limb above the pins.

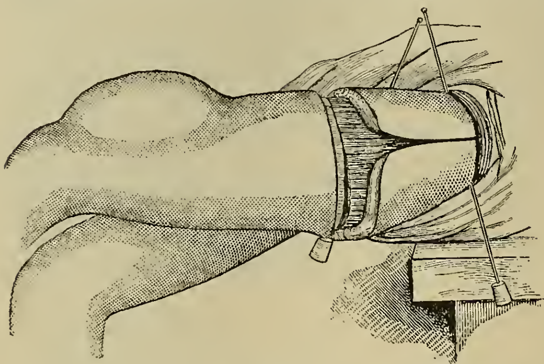

Fig. 993.—Amputation at the hip-joint: Wyeth's bloodless method.

In the *bloodless method of Wyeth* (Figs. 993, 994), after passing the pins, draining the limb of blood, and applying the band of the Esmarch apparatus, the amputation is proceeded with. The hip is brought well over the edge of the table, a circular incision is made down to the deep fascia, 6 inches below the constricting band, and is joined by a longitudinal skin-cut reaching from the band to the level of the circular incision, and the cuff is reflected to the level of the lesser trochanter. The muscles are cut by a circular sweep at the

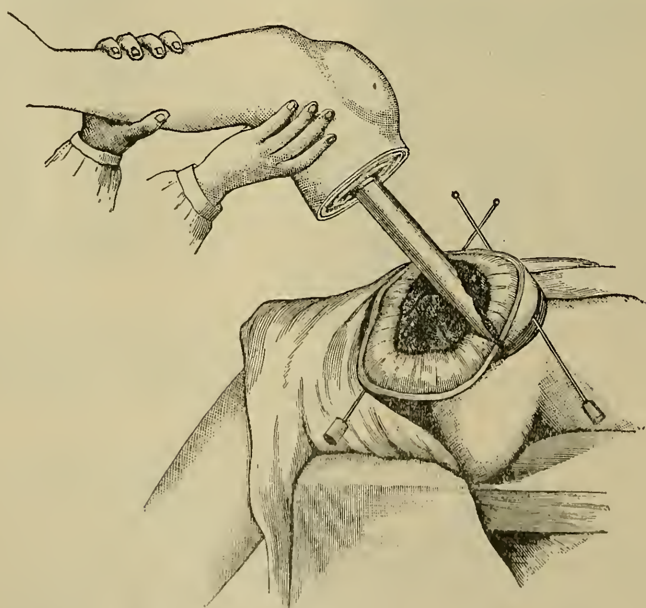

Fig. 994.—Wyeth's bloodless amputation at the hip-joint: Cuff of skin and subcutaneous fat turned back, muscles divided at level of small trochanter, bone partly stripped, and large vessels exposed for deligation.

level of the retracted cuff, the capsule of the hip-joint is opened freely, the cotyloid ligament is cut posteriorly, the thigh is bent upward, forward, and inward to dislocate the head of the bone, and, using the thigh as a handle, the round ligament is incised and the limb removed. After ligating the vessels

and introducing drainage-tubes the flaps are sewn together vertically. The old transfixion operation is practically extinct. A T-*amputation* may be

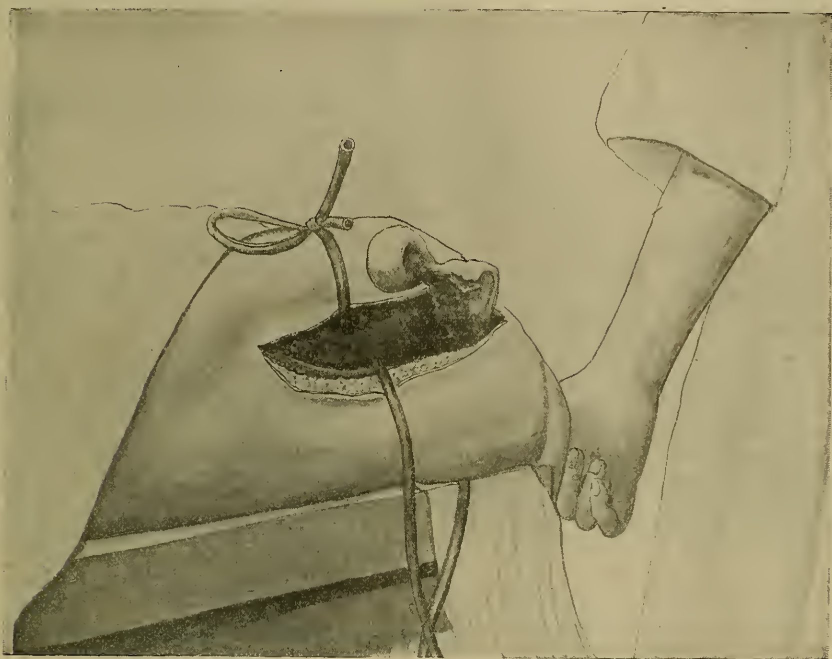

Fig. 995.—Senn's method of performing bloodless amputation at the hip-joint. Dislocation of head of femur and upper portion of shaft through straight external incision. Elastic constrictors in place, the anterior one tied (Senn).

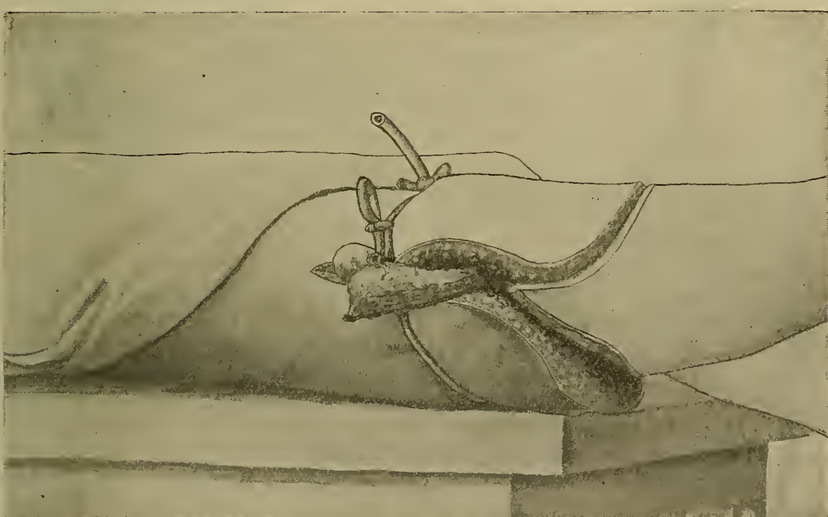

Fig. 996.—Elastic constriction completed by constricting the posterior segment of the thigh. Flaps formed, including all the tissues down to the muscles (Senn).

employed. It consists of an external straight incision down to the bone, starting over the great trochanter, down the outer side of the limb, and a

circular incision through the skin 5 inches below the constricting band, the muscles being cut by a circular sweep at the level of the retracted skin. This method affords easy access to the joint. The bloodless method of Wyeth, as applied to the hip-joint and shoulder-joint, is a notable advance in the art of surgery.

Senn's Bloodless Method.—The elder Senn has devised a method for preventing hemorrhage during amputations of the hip-joint. He makes a straight incision, about 8 inches in length, in the direction of the long axis of the femur and directly over the center of the great trochanter. This incision reaches about 3 inches above the upper margin of the great trochanter. The muscular insertions are divided close to the bone, and the thigh is flexed, strongly adducted, and rotated inward. The capsular ligament is divided at its upper and posterior aspect. While the thigh is brought into a position of slight flexion, the remaining portion of the capsular ligament is cut. Then the thigh is dislocated outward, and the ligamentum teres is cut. If this cannot be accomplished, the head of the bone is forcibly dislocated upon the dorsum of the ilium. After dislocating, the lesser trochanter and the upper part of the femoral shaft are cleared. The limb is now brought down in a straight line

Fig. 997.—Keen and DaCosta's method of interilio-abdominal amputation ("International Clinics," vol. iv, 13th series).

Fig. 998.—Keen and DaCosta's case of interilio-abdominal amputation. The shaded portion of the bone was removed ("International Clinics," vol. iv, 13th series).

with the body, the thigh is slightly flexed, a long and stout pair of forceps is inserted into the wound behind the femur and on a level with the normal situation of the lesser trochanter, and the instrument is pushed downward and inward, 2 inches below the ramus of the ischium and just behind the adductor muscles. As soon as the point can be felt under the skin, an incision 2 inches in length is made upon it, and the instrument is forced through the opening. The tunnel in the tissues is enlarged by opening the forceps. A piece of rubber tubing ¾ inch in diameter and 4 feet in length is caught about the middle with the forceps and is withdrawn. The rubber tube is cut in two at about the point at which the forceps have held it, and half of the tube is used to constrict the anterior segment of the thigh (Fig. 995) and the other half to constrict the remaining portion of the thigh (Fig. 996). Before the constricting bands are tied the limb is held vertically for a sufficient length of time to make it practically bloodless; the amputation is then completed (Senn's "Practical Surgery").

Other Methods.—John G. Sheldon ("Amer. Med.," April 19, 1902) has modified Senn's method as follows: He disarticulates the head of the femur and frees the upper part of the femur from its attachments. He then introduces a pair of long, stout artery-forceps behind the femur and clamps the femoral vessels. He forms the flap, removes the limb, and ligates the vessels. In this operation the surgeon can work rapidly and can make a flap of any size or shape, and is not hindered by a constriction apparatus; but this method does not cut off the bleeding from the obturator and the sciatic arteries.

Larrey amputated by lateral flaps, and Liston by anteroposterior flaps. Forneaux Jordan's method consists in dividing the soft parts low down, tying the blood-vessels on the face of the stump, shelling out the femur from the soft parts, and disarticulating.

Interilio-abdominal Amputation.—This very formidable operation is occasionally performed for sarcoma of the ilium. The operation was first performed by Billroth in 1891, and the patient died. Prof. Keen and I collected 19 cases, including 1 of our own. Five of these cases recovered (W. W. Keen and J. Chalmers DaCosta, in "International Clinics," vol. iv, 13th series). Our patient perished in thirty-three hours from suppression of urine and with gangrene of the parts supplied by the internal iliac artery. In some cases the entire innominate bone has been removed, in others portions of it have been left. In our cases we made the flap shown in Fig. 997, tied the internal iliac artery after rolling up the peritoneum, but spared the external iliac, kept the femoral in the flap, and sawed through the bones as indicated in Fig. 998, leaving in place the portions shown in white.

XXXIX. DISEASES OF THE MAMMARY GLAND

Hypertrophy of the Breast (Fig. 999).—This is a rare condition. It may affect one breast or both. It is most apt to appear at the age of puberty, but it may appear in childhood, adult life, or old age. The breast may attain enormous size. In Porter's case the breasts of a woman of thirty-seven were so very large that they were carried hung upon a frame ("Boston Med. and Surg. Jour.," March 3, 1892).

These very large breasts are not composed of true gland tissue, but rather of fat and connective tissue (" Diseases of the Breast," by A. Marmaduke Sheild). Hypertrophy may also occur in the male breast. In some cases hypertrophy occurs so rapidly as to merit the name *acute*. Such cases may perhaps be sarcomatous.

Treatment.—Be sure it is hypertrophy and not sarcoma, adenoma, or lipoma. Try recumbent posture, dry diet, pressure, and iodid of potash (Sheild, Ibid.). If these means fail, amputation is the only resource.

Mammillitis and Fissure.—The nipple may inflame as a result of injury, but the condition is rarely encountered except in a woman who is nursing a baby. It is most common after a first pregnancy, when the nipple is deformed or when the skin is delicate. The nipple is slightly injured during nursing, and the epithelium is macerated by the milk and saliva. If the inflammation is not arrested, a spot excoriates or an irritable ulcer forms (a fissure). A fissure is often surrounded by an area of acute inflammation, and nursing causes intense agony. Because of the pain the mother is apt to extend the intervals between nursing, and as a consequence the breasts become swollen with retained milk. The ulcer not unusually bleeds when the breast is taken by the child. Besides the fact that a fissure causes pain to the mother, it often leads to grave trouble. It is a suppurating area, and as such may lead to abscess of the mother's breast, or may impair the health of the nursing child.

Prevention of Fissure.—During pregnancy the nipples should be carefully attended to. They should be washed often in sterile water and bathed in alcohol, and if retracted, ought to be drawn out repeatedly. During the period of lactation the nipples are washed in sterile water, dried, and dusted with borated talc powder as soon as an act of nursing is completed. Washing the nipples regularly with the following solution tends to prevent the formation of a fissure: iodid of mercury, 2 gr.; alcohol, $1\frac{1}{2}$ oz.; glycerin and distilled water, of each a pint (Lepage). If a small abrasion appears, order the woman to wear a nipple-shield during nursing, and after each act of nursing to wash the part with hot sterile water, dry, and dust borated talc over the surface. If a fissure forms, wean the child at once, and dry up the milk in both breasts. It is useless to try and dry it up in one breast. Milk may be dried up by applying ointment of belladonna locally, and administering iodid of potassium internally; by strapping the breasts with adhesive plaster (Parker); or by applying to the nipples six times a day a 5 per cent. solution of cocain in equal parts of glycerin and water (Joise). The fissure is not treated by ointments. These preparations are septic, prevent drainage, and aggravate maceration. Wash the fissure twice a day with peroxid of hydrogen, dress it with gauze wet in boric acid solution (10 gr. to 1 dram of water), and cover the dressing with waxed paper. If the fissure resists treatment, touch it with lunar caustic.

Fig. 999.—Hypertrophy of breast.

Acute Mastitis and Abscess.—Acute inflammation of the breast, as a result of injury of the breast or nipple, may occur in either sex at any time of life. Very commonly in both sexes a few days after birth the breast becomes distended with a material which in reality is milk. The fluid is usually small in quantity. The process is physiological, and, as a rule, ceases spontaneously (Guelliot). If it lingers, the application of belladonna ointment will stop secretion. If the nurse meddles with the glands and tries to squeeze out the fluid, acute mastitis is apt to arise in one gland, or occasionally in both. The skin of the breast reddens, the gland swells and becomes tender and painful, the child loses its appetite and becomes feverish, restless, and sleepless. Such a condition is treated by the local use of alcohol. If pus forms, the local signs and constitutional symptoms are aggravated. Evacuate the pus, dress with hot antiseptic fomentations, and be sure that the child is well nourished. Tonics and stimulants are indicated.

A condition identical with the secretory activity of the glands of the new-born may occur in either sex at puberty. The methods of treatment are the same in both cases. As a matter of fact, at this time of life rarely more than one lobule inflames, and suppuration is most unusual.

Acute mastitis is most usually met with in a woman who is nursing a child, and is due to bacterial infection. Primipara are particularly liable to develop mastitis. So are women with deformed nipples. In most cases an abrasion of the nipple exists, and through this breach of continuity bacteria gain entrance to the breast-tissue. The abrasion may be so slight that it can only be detected when the nipple is examined through a magnifying-glass (Marmaduke Sheild). Streptococcic infections are very generally due to inoculation of a fissure of the nipple. Bacteria may pass up the milk-ducts, coagulating the milk and penetrating through the walls of the acini. Staphylococci not unusually pursue this route in reaching the breast-tissue. Occasionally causative bacteria reach the breast through the arteries (in septicemia and in septic wounds of the genital organs).

Symptoms.—There are pain, swelling, and tenderness in the breast, and in most cases a fissure or abrasion exists. There is a febrile condition. Occasionally a chill ushers in the attack.

If a case supposed to be acute mastitis proves utterly rebellious to treatment the suspicion should arise in the surgeon's mind that the condition is acute or inflamed cancer (carcinoma mastitoides, see page 1436). If such a doubt arises, a piece of tissue must be excised for microscopical study.

Treatment.—Order the patient to suspend nursing. The physician endeavors to arrest the secretion of milk. Treat the nipple as advised on page 1424. Support the breast and apply ichthyol ointment.

Mastitis may undergo resolution; it may terminate in organization and induration; it may eventuate in suppuration.

Acute abscess of the breast follows acute mastitis. There may be but one area of suppuration, or multiple foci may exist, which eventually fuse. The symptoms of mastitis, local and constitutional, are greatly aggravated. After a time the skin becomes dusky and edematous. The axillary and superficial cervical glands enlarge. The abscess will eventually open spontaneously at one or more points, leaving branching fistulæ. A superficial abscess is situated just beneath the nipple, and pus may flow from the nipple.

An intramammary abscess is in the depths of the gland. There are often nultiple foci of suppuration. Nodules are felt in the gland, pus may run from the nipple, but cutaneous redness is late in appearing.

Retromammary abscess is a rather rare condition. It may occur alone or be associated and connected with an area of intramammary suppuration. It may result from metastatis or from caries of a rib. The breast is lifted up by the fluid beneath it.

Treatment.—Open a superficial abscess by an incision radiating from the nipple. Treat as any other acute abscess. An intramammary abscess should be opened by a radiating incision, and pockets of pus should be broken into with the finger. An examination is made to determine if a retromammary abscess also exists If this is found to be the case, an incision is made at the point of junction of the thorax and mammary gland, and at the lower border of the gland. The gland is raised from the chest wall, the pus evacuated, a drainage-tube is inserted, and a few sutures are introduced. If retromammary abscess exists alone, make the last-named incision in the first place.

Chronic Mastitis.—This condition may be present in only a portion of the breast, or may attack many lobules (lobar mastitis). The ordinary form may arise after weaning a child, or may be due to a blow, to the pressure of corsets, or to numerous slight traumatisms. It may occur in the young, the middle aged, or the old. The patient has slight pain at times in the gland. Examination detects a firm, elastic area, which is somewhat tender and does not possess distinct margins. The skin is not adherent to the mass

unless suppuration occurs. If the mass is pressed against the chest by the surgeon's fingers, it becomes evident that no real tumor exists.

Treatment.—Remove any cause of irritation. Support the breast by a spica bandage. Apply ichthyol ointment During the night employ a hot-water bag. If pus forms, treat as before directed.

Chronic lobular mastitis is a condition in which numerous lobules become indurated. The real cause of this condition is unknown. It may occur at any age after puberty, and often attacks both breasts. Such a breast is apt to be painful, especially at the menstrual periods; it feels unnatural, solid, and careful examination detects numerous indurated areas, each of which is of small size. At the menstrual period the breast enlarges and new nodules may be detected. In some of these cases violent neuralgic pains are present in the gland (*mastodynia*). Chronic lobular mastitis is apt to lead to cyst formation. When cysts form fluid may occasionally discharge from the nipple.

Treatment.—Support the breast and apply ichthyol ointment or belladonna ointment. Examine the generative organs and correct any existing abnormality. Improve the general health by good food, tonics, and open-air life. In cases in which multiple cysts are known to exist the question of treatment is uncertain. There seems to be little doubt that such cases tend in some instances to eventuate in cancer. I believe that the proper treatment when multiple cysts exist is extirpation of the breast.

Tuberculosis of the Mammary Gland.—Sir Astley Cooper in 1829 wrote on "scrofulous swellings" of the breast, and Velpeau also referred to them. Nevertheless, Virchow, in his treatise on tumors, stated that the mammary gland was not subject to tuberculosis. Durbar first proved the existence of the condition by histological and bacteriological observations. Primary tuberculosis of the breast is a rare condition. If we are to judge from English and American literature, it is a very rare condition. In 1902 Bindo de Vecchi was able to report 1 case and collect 77 from literature ("Extratis della Clinica Chirurgica," No. 8, 1902). Braendle in 1906 reported 11 cases from the Tübingen clinic ("Beit. zur klin. Chir.," vol. i, 1906). Powers, of Denver, reported 4 cases ("Annals of Surgery," Feb., 1913). About 80 cases confirmed by bacteriological findings and histological study have been reported. It is seldom that both glands are involved. Tuberculosis of the breast may be secondary to tuberculosis of the skin, of related glands, of the rib, etc. It may result from some distant tuberculous lesion of bone, of joint, of lung, etc. It may be a part of general miliary tuberculosis. We consider here primary or, as Geissler named it, solitary tuberculosis, tuberculosis apparently limited to the breast in an individual free from evidences of antecedent tuberculosis, and of tuberculosis elsewhere. It occurs usually in those of excellent general health. The route of infection may be by the blood, by the lymph-ducts, and perhaps by the lymphatics from the skin or nipple. The lesion begins in the periacinous and periductal connective tissue. The ducts and acini become involved later. E. M. Von Eberts ("Amer. Jour. Med. Sci.," July, 1909) states that there is no reported case before the age of puberty, that the most advanced case reported was fifty-three years of age, that maturity of the gland and lactation predispose, and that the reported cases show the proportion of the married to the unmarried as 4 to 1. It is vastly more common in women than in men. In many cases there is a history of antecedent inflammation or abscess during lactation. In some cases there is a history of traumatism. There are two forms of the condition, and in each form, sooner or later, degeneration occurs, and fistulæ from a cold abscess arises (see page 242); these forms are *nodular* and *confluent* (Von Eberts, Ibid.). In the *nodular* form a nodule, several nodules, or many nodules arise in the glandular tissue. There is little

or no pain. If nodules are under the nipple retraction may occur. The condition is very slow in progress and a year or several years may elapse before degeneration occurs. Degeneration results in cold abscess (see page 236) and often in fistula formation. Schley has pointed out that cold abscess is a termination more common in the confluent than in the nodular type ("Annals of Surgery," 1903). In the confluent form the condition develops much more rapidly, is associated with pain, is most apt to arise during lactation, is particularly prone to abscess and fistula formation, and is liable to acute exacerbation from secondary pyogenic infection. The axillary glands are found enlarged in three-fourths of all cases of primary tuberculosis. Cases have been reported of carcinoma and of adenoma associated with tuberculosis.

Treatment.—In a very slowly developing nodular case, in which it is certain lactation will not arise, it may be considered proper to treat the condition with tuberculin, etc. (see section on Tuberculosis). In the confluent form and in cases of the nodular form in which tuberculin treatment has failed, or in which we cannot exclude the possibility of pregnancy, the breast should be removed and the glands and fat should be removed from the axilla. Most of the cases recover permanently after radical operation (Braendle, of Tübingen, in "Beit. zur klin. Chir.," 1906, Bd. 1). Powers ("Annals of Surgery," Feb., 1913) advises the thorough removal of the breast, pectoral fascia, and axillary contents, and with this recommendation I am in accord.

Cysts and Tumors of the Nipple.—Tumors are rare in the nipple, but do sometimes occur. The following growths are occasionally seen: fibroma, angeioma, papilloma, myxoma, myoma, and epithelioma. Sebaceous cysts of the nipple and areola are not very unusual. A cancer of the nipple may be a primary growth, or may be secondary to gland cancer. Primary epithelioma of the nipple presents the same general characters as epithelioma in any other part. It begins as an indurated area in the areola, or an excoriation of the nipple. Ulceration soon occurs. The ulcer is irregular in outline, has hard edges, and furnishes a foul, red, sanious, and fetid discharge. The mammary gland becomes infiltrated at an early period. The subclavian glands enlarge, and later the axillary glands. Such a growth must not be confounded with a chancre of the nipple.

Treatment of Tumors of the Nipple.—Innocent tumors are to be excised and the breast need not be removed.

Epithelioma of the nipple requires the complete extirpation of the breast, and also the clearing out of the lymphatic contents of the axilla, and possibly of the subclavian triangle.

Paget's Disease of the Nipple (*Malignant Dermatitis*).—This condition is held to be a chronic inflammation of the epithelial layer of the nipple and areola occurring in women beyond middle life, and is regarded as a not unusual precursor of epithelioma of the nipple and of duct cancer. Paget's disease is not a simple eczema, it is not associated with the usual causes and attendants of eczema, either local or constitutional, and is not cured by remedies which control the ordinary disease.

The diseased area is raw and red, and from it exudes copiously a thick, yellow discharge. In some cases Paget's disease is secondary to duct cancer, auto-infection of the nipple having been effected by the fluid flowing from the ducts. Investigations have shown the presence of psorosperms in areas of Paget's disease. I am of the opinion that Paget's disease is usually, from the very beginning, cancer.

Treatment.—Removal of the entire breast and clearing out of the axilla.

Tumors and Cysts of the Mammary Gland.—These tumors may be innocent or malignant. Tumors may occur in childhood (angeioma, sarcoma, fibro-adenoma). Malignant tumors are very rare before the age of twenty-five.

Innocent Tumors of the Mammary Gland.—The innocent tumors are: *Periductal fibroma*, *fibrocystadenoma*, *papillary cystadenoma*, *simple adenoma*, *periductal fibromyxoma*, *myxoma*, *angioma*, *lipoma*, and *enchondroma*. It is maintained by most authorities that any innocent tumor of the gland may and is apt to become malignant.

Periductal Fibroma, Fibro-adenoma.—The nomenclature of fibro-adenomata is in a state of great confusion. The name fibro-adenoma was given by Cornil and Ranvier to the same sort of growth which the younger Gross called a fibroma, Billroth an adenofibroma, and Sir Astley Cooper a chronic mammary tumor. It is doubtful if a pure fibroma ever occurs in the mammary gland. A fibro-adenoma consists of acini surrounded by fibrous tissue. Each of these structures proliferates, but the fibrous tissue does so much more rapidly than the glandular. Bloodgood ("Amer. Jour. Med. Sci.," Feb., 1908) says, "the fibro-adenoma microscopically is nothing more than an encapsulated area of normal breast tissue, in which the parenchyma, in the early stage of the tumor, is greater in amount than the normal breast. Later the parenchyma undergoes pressure atrophy and the tumor may become calcified." A growth of this character is surrounded by a capsule and is movable. It is firm, elastic, lobulated, superficially situated, and of slow growth. It is unassociated with retracted nipple, glandular enlargement, adhesion to the skin, or cachexia, and may occur at any age up to fifty, but is most common between twenty and thirty (Sir J. Bland-Sutton). Such a tumor is rarely very painful, but it may be tender on rough handling and may be painful at the menstrual period. As a rule, there is but one of these tumors in a mammary gland, but the tumors may be multiple in one gland, or one or more may exist in each gland. It is not very common for sarcoma or carcinoma to arise.

Periductal Fibromyxoma.—It is most common in young women. It may be multiple in one breast or both. It is an encapsulated, lobuled, and elastic growth, which is seldom painful, is usually small, and often remains quiescent indefinitely or even disappears. It may enlarge and even attain a large size. When it enlarges it is apt to become cystic and sarcomatous.

Treatment of Periductal Fibroma and Fibromyxoma.—Extirpation of the tumor. If a supposedly innocent growth, removed by a limited operation, was really the seat of beginning malignancy, the wound will soon thicken after healing and recurrence will be rapid. Halsted has shown that in such a case re-operation, however extensive, will not obtain a cure. Hence, it behooves us in doubtful cases, if we err at all, to err on the side of radicalism. In a case recognized as doubtful, when the growth is removed a frozen section should be made at once and be studied then and there, and the surgeon should suspend operation while he waits for the report. If the report shows that the growth is malignant, at once remove the breast radically and clean out the axilla. A tumor known to be innocent may be removed through an incision made along the junction of the mammary gland and breast, at the lower margin of the gland, as Thomas proposed, or, better, at the edge of the outer hemisphere, as advocated by Warren ("Annals of Surgery," June, 1907). The incision exposes the fibers of the great pectoral muscle, the gland is raised from the muscle, and its posterior surface exposed. Any growth is exposed by an incision from center to periphery and this incision is exploratory. Warren removes an innocent tumor, a cyst, or cysts by a V-shaped incision, the apex of the V being at the center of the gland, and he wisely insists that the tumor is not to be dissected out. Several radiating incisions may be necessary to explore a cystic breast. The V-shaped space from which the tumor or cyst was removed is closed by a double row of catgut sutures. Incisions for exploration seldom need to be closed by suture. The gland is sutured to the outer edge of the pectoral fascia, and a row of sutures is inserted through the deep layer of the superficial fascia.

Warren calls this operation *plastic resection of the breast.* It leaves the patient free from deformity.

Fibrocystadenoma or **cystic adenoma** (**adenocele**) is a rare form of slowly growing tumor, which is apt to attain a large size, which is nodular in outline, hard to the touch, and firmly attached to the mammary gland, but mobile upon the chest. A cystic adenoma has a distinct capsule. This form of tumor is painless, and is most apt to occur in women between thirty and forty who have borne children. The growth is adherent to the skin, but the cutaneous surface is not discolored, the cutaneous veins are not distended, the axillary glands are not enlarged, and the nipple is not retracted. From the walls of the dilated acini papillomatous growths are apt to arise (intracystic vegetations). The growth may be a precursor of cancer.

Treatment.—Radical removal of breast and clearing of axilla.

Papillary Cystadenoma.—This condition is often called villous papilloma or duct papilloma. There is much more epithelial proliferation than in the fibrocystadenoma, and the warty masses project into the cyst cavities. These growths are firm, grow slowly and painlessly, and seldom fluctuate. They do not adhere to the skin, attain a large size, or cause glandular enlargement. They are situated near or under the nipple, and occur particularly in middle life. Discharge of serous fluid from the nipple is a common symptom. In many cases there is a bloody discharge. The condition tends to become cancerous.

Treatment.—The danger that duct cancer will arise is so great that the old operation of excision of the tumor should give way to radical removal of the breast. In any duct growth with a serous discharge from the nipple it is wise to remove the breast and clear the axilla. If the discharge is bloody that radical procedure is imperative.

Simple Adenoma.—This is a very rare tumor. It occurs in young and middle-aged women. It is soft, nodular, and freely movable. It does not adhere to the skin and does not cause lymphatic involvement. It consists of glandular acini and a very delicate stroma of connective tissue. It tends to become cancerous.

Treatment.—Extirpation of the tumor. Touch the wound with chlorid of zinc solution (10 gr. to the ounce) in order to destroy cells which might lodge and grow.

Myxoma is a rare tumor, and only occurs in a person of middle age or beyond. The growth is solitary, is soft, may be round or lobulated, and occasionally fungates. The nipple is not retracted, the superficial veins are not distended, and the axillary glands are not enlarged.

Treatment.—Removal of the mammary gland.

Angioma.—This form of tumor is very rare. It may arise secondarily to a nevus of the skin (Sir J. Bland-Sutton). The diagnosis of angioma of the skin is readily made. In a cavernous angioma of the breast it will be found that the tumor can be lessened in size by pressure, and will be increased in size by coughing, laughing, and holding the breath. Pulsation may be detected and a bruit may be audible.

Treatment.—For treatment of nevus see page 366. If a cavernous angioma exists in the mammary gland, it will be necessary to extirpate the gland.

Lipoma and *enchondroma* occasionally occur in the breast.

Cysts of the Mammary Gland.—**Involution cysts** (*cystic degeneration of the mamma*) occur in women who are approaching the menopause. Such cysts occur earlier in those who are sterile than in those who have borne children, and may arise after chronic mastitis. The parenchyma of the gland undergoes atrophic change, but the ducts remain, become blocked and dilated. Numerous small cysts form, and both glands, as a rule, suffer. Villous growths

may arise in the walls of the ducts. In some cases there is much white fibrous tissue between the cysts (cystic fibroma).

The subjects of this disease are often nervous, hysterical, and despondent. One or more ill-defined indurations are detected. Frequently there is a history of discharge from the nipple and of attacks of lancinating pain in the breast. Cystic breasts are dangerous, because the intracystic vegetations are liable to eventuate in duct cancer. One-fourth of these cases are cancerous when first seen (Speese, quoted by Primrose in "Amer. Jour. Med. Sci.," Jan., 1913).

Treatment.—In such cases, after confirming the diagnosis by an exploratory incision, remove the entire breast.

Lacteal cyst (galactocele) is an accumulation of milk brought about by blocking of some of the milk-ducts. It usually arises soon after the delivery of the child, but may not be noted for months or even several years after child-bed. It grows rapidly from the time it is first detected. A large quantity of milk may collect, and rupture of the cyst walls may occur, the fluid passing into the glandular connective tissue.

A galactocele is rounded, fluctuates distinctly, and increases in size during nursing. There is little or no pain. In some cases the contents of the cyst coagulate and a solid mass is formed.

Treatment.—Incision and drainage.

Hydatid cysts are rare, but do occasionally occur. There are 33 positive cases on record (Le Conte, in "Amer. Jour. Med. Sci.," Sept., 1901). A small, hard, movable, and painless mass appears in the mammary gland. Usually it gradually increases in size, but it may grow rapidly for a time and then remain apparently almost stationary for a period. If rapid growth takes place there is always pain, and pain is usual in any case when the cyst attains considerable size. Fluctuation is often absent and crepitation is never obtained (Le Conte). Suppuration is apt to occur and sinuses may form.

Treatment.—A small and recent cyst may be extirpated. If the cyst is not recent, but is fairly large and adherent, incise, evacuate, and pack with gauze. If the cyst is large and adherent, but is surrounded by considerable breast tissue, partially amputate the breast. If the cyst is large and the breast practically destroyed, or if the nipple adheres to the cyst, remove the mammary gland (Le Conte, Ibid.).

Malignant tumors of the mammary gland are ten times more common than innocent tumors. We should regard every palpable tumor in the gland as malignant until it is proved to be innocent. In other words, we reverse the rule of jurisprudence. We regard every tumor as guilty of malignancy until its innocence is proved. If the mistake is made of regarding an innocent tumor as malignant, the woman loses her breast needlessly. If a malignant tumor is regarded as innocent the woman loses her life needlessly. "The fact that malignant degeneration of benign growths in the breast is of frequent occurrence is obviously another convincing argument for the removal of all breast tumors. A recent study by Speese showed that no less than 26 per cent. of the cases of chronic cystic mastitis (that is, that form of 'abnormal involution' occurring at the menopause) examined by him showed malignancy. So, too, cyst adenomata are found associated with carcinoma, the frequency of such association being placed by some authors as high as 15 per cent. Inflammatory conditions of the breast resulting in mastitis are often found in the early history of cancer cases. All these facts point conclusively to the frequent occurrence of malignant degeneration in benign growths of the breast" (A. Primrose, Loc. cit.).

Sarcoma of the mammary gland is a very rare growth (not over 3 per cent. of breast tumors). It may occur at any age from puberty to old age. It was long thought to be most common from twenty to thirty-five years

of age, but Rodman's investigations show that one-half the cases occur in the fifth decade of life (Rodman on "Diseases of the Breast"). The growth may be composed of round cells or spindle cells; both varieties may be present, and myeloid cells may be found. Circumscribed sarcoma arises usually between the ages of twenty and thirty; it is firm to the touch, as it contains much fibrous tissue, is painless, does not grow very rapidly, glands are seldom involved, and there is no cachexia. The nipple is not retracted. The growth may adhere to the skin. If it is composed of giant cells or spindle cells it will rarely return after extirpation of the breast.

Diffused sarcoma is composed of small round cells, arises in the center of the breast, and grows with great rapidity. It is most commonly met with

Fig. 1000.—Scirrhous carcinoma (J. Collins Warren).

about the age of thirty-five, and a history of injury can often be elicited. The tumor is soft, some parts being softer than others because of cyst formation. It is usually mobile upon the thorax, though it soon becomes adherent to the skin. The tumor reaches a very great size, and soon fungates through the skin. There is little or no pain. The cutaneous veins over the tumor are distended, the nipple is not retracted, and the axillary glands are not often enlarged. Diffuse sarcoma is apt to recur after removal.

Treatment.—Remove the breast, and if the muscles of the chest wall are infiltrated, remove them. The axillary glands should be removed whether they are enlarged or not. Operation will not cure when metastases exist. If the case is inoperable, we can try the use of Coley's fluid. If the toxins

of erysipelas fail to arrest the progress of the disease, keep the patient as comfortable as possible by the administration of cocain and morphin.

Endothelioma.—This is a very rare tumor. I have had 1 case of it. The diagnosis cannot be made from carcinoma.

Treatment.—As for cancer.

Carcinoma or Cancer of the Mammary Gland of the Female (Fig. 1000).—The great majority of mammary tumors are cancerous. Cancer is due to proliferation of the epithelium of the acini (acinous cancer) or of the ducts (duct cancer).

Acinous cancer is vastly more common than duct cancer. Usually there is much connective tissue and but little parenchyma in the growth (scirrhous cancer). In some cases there is little connective tissue and much parenchyma (encephaloid or medullary cancer). If colloid degeneration of the parenchyma or stroma occurs, the growth is spoken of as colloid cancer.

Scirrhus (Figs. 1000 and 1001), the common form of acinous cancer, is almost as hard as stone. On section it is concave, and Sutton says "resembles an unripe pear." The tumor is without a capsule, and the epithelial cells are surrounded by masses of fibrous tissue. Portions of tissue even some distance away from the tumor proper contain foci of proliferating embryonic epithelial cells. In atrophic or withering scirrhus the fibrous stroma contracts and epithelial cells undergo fatty degeneration.

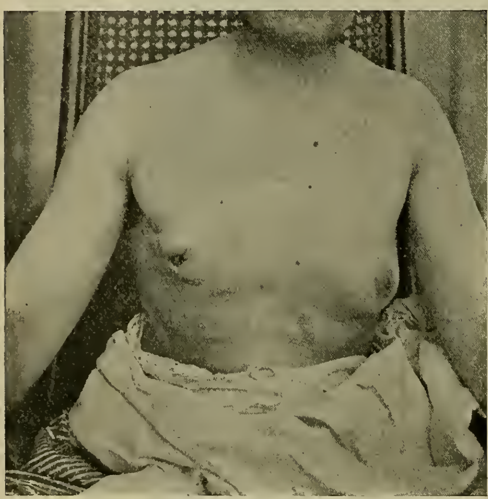

Fig. 1001.—Scirrhous carcinoma of right breast showing retraction of nipple (Dr. Blanck's patient).

Halsted in 1898 described *adenocarcinoma.* It is the initial movement in the direction of unrestrained epithelial proliferation, and sections of the tumor show the formation of tubular acini. The most characteristic sections resemble adenoma. Adenocarcinoma is not the common form of breast cancer. In the common form the proliferating epithelium attains no resemblance to glandular structure, but multiplies irregularly in connective-tissue spaces or lymph-spaces.

Causes and Symptoms.—Scirrhus is more common among women who have borne children than among those who have not. Heredity is manifest in only about 10 per cent. of cases. The younger Gross found it in 1 case out of 9. Trauma has no apparent influence in producing cancer. The disease is rare before the age of thirty-five, and is most common between forty-five and fifty. The author operated for scirrhus of the breast on a woman only twenty-seven years of age. Henry saw a woman of twenty-one with cancer. It is frequently met with in the aged. These tumors are rare in the negro race. A hard nodule is found in the breast, usually under the nipple, but possibly far away from it. The growth is nodular, and is immobile from the beginning. In a large, fat breast there is often a deceptive sense of mobility, because some of the breast tissue moves with the tumor. The cancer may have been present for a considerable time before being discovered. Sometimes widespread lesions develop from a small or an undiscovered breast cancer (pleural effusion, enlarged glands of the neck, disease of the spinal cord, bones of the

skull or brain). In obscure lesions of bones and viscera examine the mammary glands, because the trouble might be due to metastasis from an undiscovered carcinoma of the breast. The glands of the armpit always and soon become diseased, the glands above the clavicle often enlarge, and the arm may swell. Growth may arise within the chest, either by lymph regurgitation from the axillary and subclavian glands, or directly through the chest walls to pleura and lung or to mediastinal glands. Oelsner and Poirier showed that there is a lymph tract running from the breast to glands within the thorax, passing through the great pectoral muscle and "the fourth interspace at the level of the costochondral articulation" (Primrose, in "Amer. Jour. Med. Sci.," Jan., 1913). "Fortunately, these glands are not frequently involved, a circumstance which may be accounted for by the atrophy of this channel in senile mammæ, in which cancer usually develops (Poirier)" (Primrose, Ibid.). Retraction of the nipple is present in over one-half of the cases. It occurs when the growth is near the nipple, and is due to the contracting fibrous tissues of the tumor pulling on the milk-ducts. If the growth is far away from the nipple,

Fig. 1002.—Carcinoma of right breast. Lesion first noticed six months before photograph was made.

a dimple is apt to form on the skin of the breast because of the pulling upon the suspensory fibers. Neither retraction of the nipple nor a cutaneous dimple proves the existence of cancer. One or both may be noted in a breast containing a scar (from a wound or a healed abscess), in tuberculosis of the breast, and in mammary syphilis. The dimple is not due to adhesion between the tumor and the skin. It is noted even when the tumor is far away from the skin. It may not be obvious unless the gland is moved to and fro or unless the skin over the breast is pushed in various directions. When this is done it becomes evident that the skin, at a certain point, is held inward. The dimple is a very valuable early symptom.

Glandular enlargement in the axilla soon follows the appearance of a scirrhus; the glands become very hard and adherent. In over 60 per cent. of persons the glands of the axilla are felt to be enlarged when the patient first comes for treatment. Because the surgeon cannot feel enlarged glands is no proof that there are none. As a matter of fact, the glands are usually involved within two months of the beginning of the disease, but the involvement can rarely be detected externally until months later. Enlargement of

the axillary glands is followed by enlargement of the glands in the posterior cervical triangle and in the mediastinum. Herbert Snow has shown that the blocking of the axillary glands often leads to regurgitation of lymph containing cancer-cells, the cells being thus deposited in the head of the humerus and the thymus gland. Cancer in the thymus and in the mediastinal lymph-glands after a time causes a projection of the sternum (the *sternal symptom*). When the axillary lymphatics are extensively involved the arm swells from obstruction to the lymph-flow (lymphedema) or pressure upon the vein. If there is lymphatic obstruction the skin of the breast becomes pitted and resembles *pig skin*. The skin is actually cancerous or soon becomes so by infiltration. Each pit is the opening of a sweat-gland. The sweat-duct is held down by contracting fibrous tissue. This condition is termed *peau d'orange*, or pigskin saddle appearance. The tumor usually grows rather slowly unless lactation is established; then it grows with

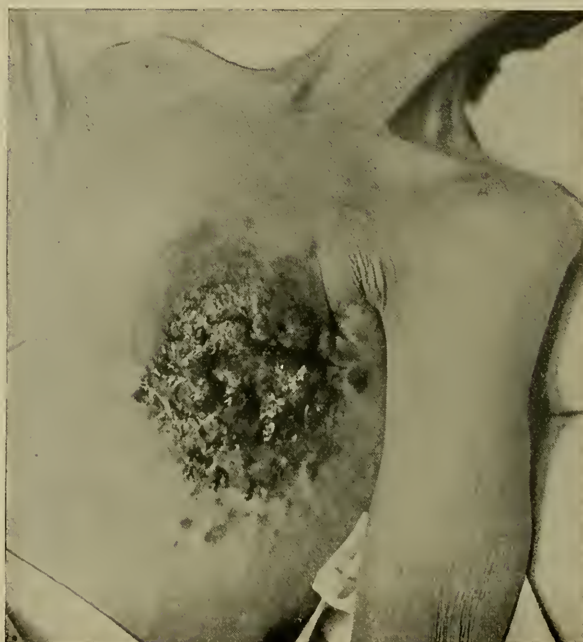

Fig. 1003.—Recurrent carcinoma. Cancer en cuirasse.

frightful rapidity. As it grows it infiltrates adjacent structures (the pectoral fascia, pectoral muscles, subcutaneous cellular tissue, and skin). When a tumor becomes adherent to the skin the skin becomes congested and of a dark purple hue. When the skin is destroyed, an ulcer forms, and around this ulcer the skin becomes red and filled with cancerous nodules, which feel like shot in the skin. Metastases are apt to occur into the bones, liver, brain, pleura, lung, spine, thymus gland, and rarely the eye. The pleura and lung may be attacked by direct spread of the growth through the chest wall, from infected mediastinal glands, or by lymph regurgitation from the axillary and subclavian glands.

Pain, absent at the start, is usually present later in scirrhous carcinoma. It is lancinating and neuralgic in character, and not brought on or increased by handling. It ceases if colloid degeneration begins. The general health is usually unimpaired until ulceration takes place, when cachexia arises. In 1792 Howard described the condition which Velpeau called

particular attention to in 1838 as a deep cancer of the integument due to a cancerous state of the deep cutaneous lymphatics. Velpeau named it *ligneous cancer* and also *cancer en cuirasse* (Figs. 1003 and 1004). The cancer en cuirasse of Velpeau is a condition in which the lymphatic vessels

Fig. 1004.—Cancer en cuirasse.

of the skin are distended because of obstruction. The skin thickens as in elephantiasis. The blocked-up lymph contains cancer cells and the skin early becomes nodular and cancerous. In most cases the condition is secondary, but primary cases have been reported. The condition may arise from cancer in the breast or may follow an operation for cancer of the breast. The skin of the chest becomes thick and rigid like a leather cuirass. The growth adheres and the soft parts come to adhere to the chest wall. The skin is very extensively invaded. In this condition the chest wall is fixed, respiration is difficult, temperature is commonly somewhat elevated, and there is probably a pleural effusion. The corresponding upper extremity is usually the seat of great swelling from hard edema.

Fig. 1005.—Recurrent carcinoma of the breast.

In *atrophic* or *withering scirrhus* the breast becomes very small. In some cases the contraction is so great that it seems as though the mammary gland had been removed. The duration of scirrhus, when left to run its course, varies, but the disease generally produces death within two and a half years.

Occasionally it causes death within a year. In atrophic scirrhus the patient may live for many years.

Duct cancer is not a common growth. It arises from the duct walls in conditions of cystic degeneration of the mammary gland. The tumor is softer than the acinous growth and is not nodular. There is no pain, no retraction of the nipple, no skin dimple. Serous or bloody fluid may often be squeezed from the nipple. A duct cancer grows and infiltrates less rapidly, and involves adjacent glands later than does an acinous growth.

Carcinoma mastitoides, *acute cancer*, *brawny cancer*, or *inflamed cancer* is a condition originally described by Volkmann in 1875 under the name of *mastitis carcinoma*. It comes on almost suddenly, grows very rapidly, causes violent irritation, and hence widespread infiltration by small cells. The condition resembles inflammation (Edward A. Schumann, in "Annals of Surgery," July, 1911). In this condition the surgeon cannot make out the outlines of a distinct tumor, but the entire breast is hardened and enlarged, and the skin of the breast is reddened, infiltrated and edematous, and adheres to the gland. There is often pain and heat.

Fig. 1006.—Ulcerating scirrhous carcinoma.

Anatomically related glands enlarge. The disease is most apt to arise late in pregnancy or during lactation and is most common in rather young women. It may be limited to one breast, but both breasts may be involved, successively or simultaneously. The nipple may or may not be retracted. Slight elevation of temperature is usual.

There is rapid metastasis, profound toxemia, and early death. Death occurs in less than a year, perhaps in a few weeks. Billroth's case died in six weeks after the discovery of the cancer.

Any persisting case of supposed acute mastitis should make us suspicious. In such a case excise a piece of tissue for examination. In cutting out the piece small abscess cavities may be discovered even when the condition is cancerous. Schumann (Ibid.) says there are only 13 reported cases of carcinoma mastitoides. Since Schumann's paper Morris Booth Miller reported a case ("Annals of Surgery," May, 1913). I showed a case to the class at Jefferson Hospital in the winter of 1912–13. The woman was pregnant and both breasts were involved. She perished miserably a few months after the onset of the disease and a few weeks after her confinement.

Cancer of the Male Breast.—This condition is seldom met with, though I believe it to be more common than is generally supposed. I have seen 4

cases within the last ten years. Each patient was in the early forties; neither complained of pain. In one the breast had been extremely large from early years. In each case the growth was indurated, but in neither was there any retraction of the nipple. The condition in each patient was scirrhous carcinoma. Warfield has collected 32 cases from literature and has added 5 others ("Bull. of Johns Hopkins Hosp.," Oct., 1901). The patients were between forty and seventy years of age; 8 gave a history of injury; in 9 cases there was pain, and in 12 the nipple was retracted. Palermo has collected 750 cases of tumor of the male breast ("Semaine Médicale," May 20, 1908) and 649 of them were cancerous.

Treatment of Carcinoma of the Mammary Gland.—The treatment is early and thorough operation; the earlier and the more thorough, the better. The older surgeons operated simply to prolong life a few months; the modern surgeon operates with the hope of curing the patient. The mortality of the operation is surprisingly small. It is certainly under 2 per cent. Rodman's statistics (2133 operations performed since 1893 by twenty-one American surgeons) show a mortality of less than 1 per cent. I have personally lost 5 patients in over 250 operations. In 1878 Billroth's statistics showed only 8 cures in 143 cases. In 1896 W. Watson Cheyne reported 12 cures out of 21 cases (57 per cent.). His cases now show 54.8 per cent. alive and well from six to thirteen years after operation. Depage's statistics show that 48 per cent. of cases passed the three-year limit ("Presse Médicale," Oct. 21, 1908). Greenough, Simmons, and Burney consider 320 cases operated upon radically ("Annals of Surgery," July, 1907); 88 cases passed the three-year limit.

E. S. Judd ("Jour. Amer. Med. Assoc.," April 27, 1912) publishes the following statistics from the Mayo Clinic. He says: "The prognosis as to the probability of a cure in a case of carcinoma of the breast will depend—1, on the length of time the neoplasm has been developing; 2, on the degree of outlying involvement; 3, on the activity of the gland, which will be determined by the age of the patient and the relation to a period of lactation; and, 4, on the thoroughness of the removal of the gland-bearing fascia.

"Data Collected from the Mayo Clinic on 518 Cases of Carcinoma of the Breast, From January 1, 1890, to January 1, 1900:

Average age	55 years, 6 months.
Oldest	75 years.
Youngest	21 years.
Number of cases operated on over ten years before:	
Alive and well	21 (23.5 per cent.).
Dead	23
Not heard from	45
Total	89
Number of cases operated on over five years before:	
Alive and well	74 (30 per cent.).
Dead	76
Not heard from	89
Total	239
Number of cases operated on over two years before:	
Alive and well	233 (44 per cent.).
Dead	134
Not heard from	151
Total	518"

Bloodgood ("Amer. Jour. Med. Sci.," Feb., 1908) sets forth Halsted's statistics: "The statistics in Halsted's Clinic up to the present time show that among 210 cases, in which three years or more have passed since the operation, 42 per cent. are apparently well. If we consider the cases in which the axillary

glands, studied microscopically, showed no evidence of metastasis, 61 cases, or 85 per cent., are well. In cases in which the axillary glands showed metastasis (110), 30 per cent. remained free from recurrence for three years. When the glands in the neck showed metastasis (40 cases), only 10 per cent. remained well for three years. In all of these groups metastasis has been observed after an interval of three years of apparent cure. Such late metastasis may take place up to eight years after operation. Excluding these cases of late recurrence, the definitely cured in these three groups is reduced to 75, 24, and 7 per cent. respectively, or, for all cases together, 35 per cent. I have not time to give the facts, but there is evidence to indicate that when the microscope fails to demonstrate metastatic cancer cells in the lymphatic glands in the axilla, this is not a positive proof that metastasis has not taken place, and for this reason and others, which space prevents me from stating, there should be no restriction in the complete operation for carcinoma of the breast." It will be observed that of these 40 cases, with involvement of neck and axilla, only 4 passed the three-year limit. If they had not been operated upon, statistics would have been bettered. The surgeon who would not operate on such cases would have a higher percentage of cures for his statistics, but he would have sacrificed to statistical glory these 4 cases. If there is the *slightest* doubt of the diagnosis, make an exploratory incision before making the incisions for the removal of the breast (see Dawbarn's remarks on the deceptive signs given by thick-walled abscesses in the "Annals of Surgery," March, 1908). A frozen section can be made and examined in a few minutes, and this procedure is demanded in a doubtful case. If the mass proves to be cancer, I always pack in a piece of gauze just wrung out of boiling water and go on at once with the removal of the breast. As Dawbarn shows, this method seals up the open mouths of lymphatics. A radical operation should remove the breast and much of the skin above it, the pectoral fascia, the pectoral muscles, the fat and glands of the axilla, and the fascia over the serratus magnus. As Cheyne says, remove all the glands along the axillary vein and lift up the vein at the apex of the axilla and remove the glands and fat behind it. The sheath of the vein should always be removed. Cheyne points out that the line of spread must be traced upward along the vessels and nerves and downward along the external respiratory nerve of Bell ("Lancet," March 12, 1904). If three years after an operation there has been no return, we regard the case as cured (Volkmann's limit). As a matter of fact, recurrences are noted after five years, and this limit should be used instead of three years. It is true that 80 per cent. of those passing the three-year limit remain free from recurrence. Over 90 per cent. of those passing the five-year limit remain free. Coley reported 65 cases of recurrence—15 per cent. recurred after three years and 6 per cent. after fourteen years. Ransohoff collected 10 cases of recurrence during the seventh and eighth years, 2 each after the ninth, tenth, eleventh, twelfth, and fifteenth years, and 1 each after various intervals, from fifteen to twenty-five years. Martin suggests that these later so-called recurrences are really new growths in persons predisposed to cancer ("Annals of Surgery," Oct., 1908). Certain cases are unsuitable for a radical operation: cases in which metastases exist; cases of *cancer en cuirasse;* cases with mediastinal involvement; cases where axillary involvement is very great. Cheyne would also rule out cases in which large glands may be felt above the clavicle, believing that in such cases the mediastinal glands must be cancerous.[1] Operation is well-nigh useless for carcinoma mastitoides.

Halsted's Operation.—Halsted performs a very radical operation. He removes suspected tissue *in one piece,* and thus prevents carcinoma cells falling into the wound, for it is well known that if such cells should fall

[1] See "Objects and Limits of Operation for Cancer," by W. Watson Cheyne.

into the wound they may grow just as may a graft of healthy epithelium. The neck, shoulder, arm to the elbow, the entire surface of the chest down to the waist, both breasts, the axilla, the side and the back of the diseased side must be sterilized. It is necessary to have, besides scalpels and the ordinary instruments for an operation, a great number of hemostatic forceps (80 to 100). Place the patient recumbent, with a sand-pillow under the shoulder of the affected side. The shoulder is right at the edge of the bed, and a nurse holds the arm from the side, keeping it at a right angle with the body. Halsted's operation is performed as follows:[1] The skin-incision is made as shown in Fig. 1007, and is carried at once through the fat. The triangular skin-flap (*a*, *b*, *c*) is turned down. The costal insertions of the great pectoral muscle and the muscle are split between the clavicle and costal portions and up to a point opposite to the scalene tubercle, and at this point the clavicular portion of the muscle and the tissue overlying it are cut through close to the clavicle, and the apex of the axilla is at once exposed. The cellular tissue under the clavicular portion of the muscle is dissected

Fig. 1007.—Halsted's operation for carcinoma of the breast: the first incision.

from the muscle, and the splitting of the muscle is continued on to the humerus. The part of the muscle to be removed is cut through close to its humeral insertion. The whole mass circumscribed by the first incision (skin, breast, areolar tissue, and fat) is raised with considerable force in order to put the submuscular fascia on the stretch as it is stripped from the thorax close to the ribs. It is well to include the delicate sheath of the pectoralis minor muscle. The lower and outer boundary of the lesser pectoral having been passed and exposed, the muscle is cut at a right angle to its fibers and a little below the middle. The tissue over the pectoralis minor muscle near its coracoid insertion is divided as far out as possible, and is then reflected inward to prepare for the reflection upward of this part of the minor muscle. The upper portion of the minor muscle is retracted upward. Some surgeons do not remove the lesser pectoral muscle. I believe it should be removed, because the axilla can then be more easily and rapidly cleared. The removal of the muscle does not impair arm movements, and its retention leads to the formation, when healing is complete, of a cord-like band in front of the axilla. (See Douglas Drew, in "Brit. Med. Jour.," May 17, 1902.) The small blood-vessels under the minor muscle are carefully separated from it, are dissected out very clear, and are ligated close to the axillary vessels. Having exposed the subclavian

[1] "Johns Hopkins Hosp. Reports," vol. iv; "Annals of Surgery," Nov., 1894.

vein at the highest possible point below the clavicle, the contents of the axilla are dissected away with a sharp knife and the vein and its branches are stripped absolutely clean. The loose tissue about the artery and the nerves should also be removed. When the vessels are cleared, the axillary contents are rapidly stripped from the inner walls of the axilla and the lateral wall of the

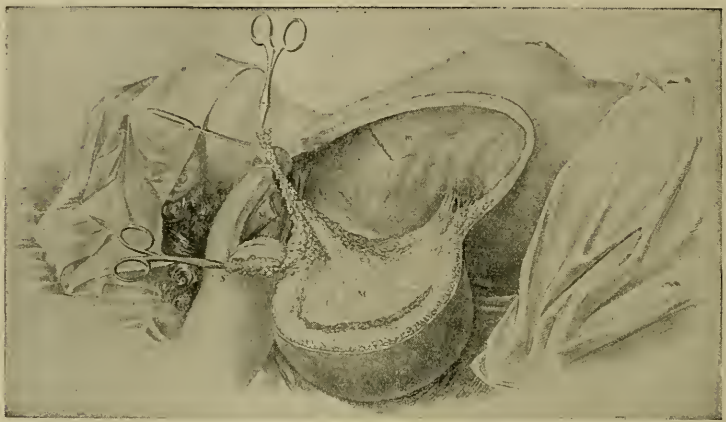

Fig. 1008.—Halsted's operation for carcinoma of the breast: The mass turned down.

thorax (Fig. 1008). The fascia which binds the mass to the chest is cut loose to the ribs and the serratus magnus muscle. Just before reaching the junction of the posterior and lateral walls of the axilla an assistant draws the triangular flap of skin outward in order to spread out the tissue which lies upon the subscapularis, teres major, and latissimus dorsi muscles. The operator cleans the posterior wall of the axilla from within outward. The subscapular vessels are clearly exposed, and are caught before they are cut. In some cases the subscapular nerves are removed, in others they are permitted to remain. Having passed these nerves, the mass is turned back into its normal position and severed from the body of the patient by a stroke of the knife from *b* to *c*, repeating the first cut through the skin. Every bleeding point, however small, is tied with fine silk. From 60 to 100 ligatures or even more may be required.

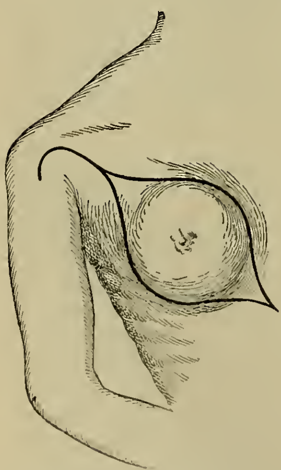

Fig. 1009.—The younger Senn's incision for amputation of the breast.

After the completion of the operation the wound into the axilla is closed with a subcuticular stitch of silver wire; if a cut has been carried above the clavicle, it is closed in the same manner, and the edges of the elliptical opening are brought nearer together by a purse-string subcuticular stitch. Thiersch grafts cut from the patient's thigh are used to cover the gap. Silver-foil is placed over the wound, this is covered with gauze, bandages are applied, and the dressing is overlaid by a plaster-of-Paris bandage, which includes the head, neck, chest, and arm. The area from which grafts were taken is dressed with sterile gauze or an ointment containing boric acid.

Formerly I did not open the subclavian triangle. I believed that these glands were involved only from the axillary lymphatics, that when they were involved the mediastinal glands were sure to be affected (the route to them

being more direct) and operation was certain to be useless. When the subclavian glands are involved from the axillary lymphatics this is true, but in some cases they are involved by way of the direct lymph paths from the mammary gland. In such a case the mediastinal glands may be free, and cleaning out the subclavian triangle may save the patient. I always open the subclavian triangle and clear out fat and glands if no glands or only a few small glands were palpable before operation. If there is a large glandular mass in the

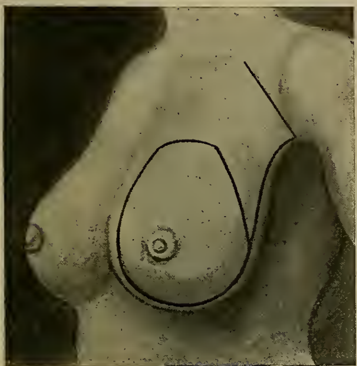

Fig. 1010.—Jabez N. Jackson's incision for removal of the mammary gland.

Fig. 1011.—Method of approximating flaps after breast amputation.

triangle, operation is useless. I always open the triangle if the tumor of the mammary gland is in the upper hemisphere, or if I discover enlarged glands at the apex of the axilla, whether there are or are not small palpable glands above the clavicle.

The Younger Senn's Incision.—A very useful incision is that described by the younger Senn, and shown in Fig. 1009. The breast is circumscribed by two curvilinear incisions which meet above, at the border of the great pectoral muscle. The incision is continued a little internal to the outer border of the muscle to about 1 inch above the apex of the axilla, when it is curved outward in the deltoid region, and terminates at the level of the apex of the axilla. The breast is removed from the wall of the chest, and is then suspended by axillary glands and fat, which are removed *en masse.*[1] This incision gives a free exposure, opens the axilla from in front, enables the surgeon quickly to locate and freely expose the axillary vein, and the resulting scar does not materially limit the motions of the arm.

Fig. 1012.—Warren's incision for removal of the mammary gland.

Jackson's incision (Jabez N. Jackson, "Jour. Amer. Med. Assoc.," March 5, 1906) is shown in Fig. 1010. The axilla is entered from above, a quadrilateral flap of skin is raised, and is subsequently pulled down to and inclosing the wound (Fig. 1011).

Warren's incision is shown in Fig. 1012. It enables the surgeon to close the wound.

[1] See the younger Senn in "Jour. Amer. Med. Assoc.," May 27, 1899.

Willy Meyer's Operation ("Jour. Amer. Med. Assoc.," July 29, 1905).—For the last few years I have been performing the operation devised by Willy Meyer. I consider it a most excellent procedure, with distinct points of superiority over other plans. We owe to Gerster the principal of opening the axilla in the beginning of the operation in order to prevent the diffusion of cancer cells and so diminish the chance of rapid recurrence. Gerster's paper was published in the "Amer. Jour. Med. Sci." in 1888. The younger Gross, in his later years, used to open the axilla first when there was an axillary mass, but he did it in order to determine in the beginning of the operation if the axillary mass was really removable. Willy Meyer emphasizes the value of his procedure in lessening hemorrhage. In Meyer's operation two flaps are formed by the skin-incision (Fig. 1013)—a lower and an upper flap. The incision for the formation of the lower flap begins at the point of insertion of the great pectoral muscle on the humerus, and is carried downward and inward $\frac{1}{2}$ inch

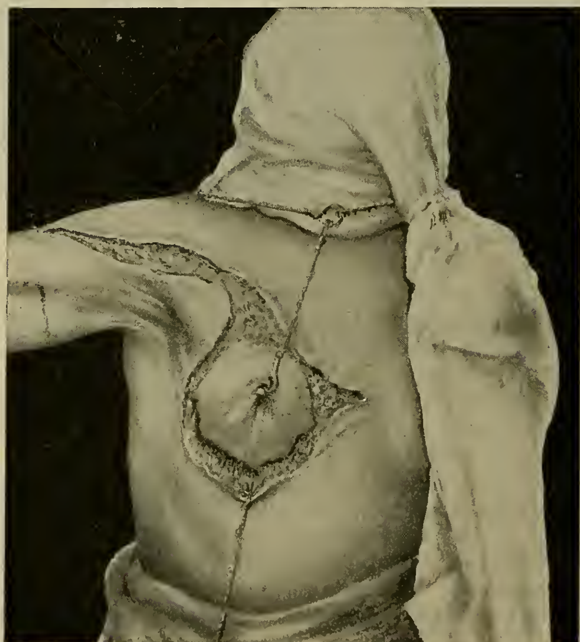

Fig. 1013.—Willy Meyer's operation for carcinoma of the breast. Skin incision as practised since 1898.

above the border of the muscle and parallel to it. When the incision reaches the base of the mammary gland, it is carried along the lower margin of the gland, and it ends over the sternum, a little beyond the midline (Fig. 1013). The lower flap is separated and turned down, a quantity of subcutaneous fat being allowed to remain attached to the breast. This turning down is carried to the border of the latissimus dorsi muscle, to the axillary cavity, and to the chest wall. Meyer then directs that the border of the latissimus dorsi be followed down to the serratus anticus major, and upward to the mass of fat that enters the bicipital sulcus of the arm. The fat is removed from the anterior border of the muscle by blunt dissection. This anterior lower wound is then packed with gauze.

The surgeon next forms the upper flap by uniting the inner and outer ends of the first incision with another incision carried along the upper margin of the breast (Fig. 1013). In this flap, as in the other, the surgeon leaves as

much subcutaneous fat adhering to the breast as he can spare without inducing the danger of skin necrosis. This upper flap is raised progressively until the cephalic vein is reached and there is exposure of the lower surface of the clavicle with the sternoclavicular articulation. Meyer directs that the tissues covering this articulation shall not be disturbed.

After the formation of these two flaps the next step in the operation is the division of the tendons of the two pectoral muscles and the exposure of the axillary and subclavian veins. Meyer advises that the cephalic vein be followed up until the insertion of the great pectoral muscle into the humerus is found. The tendon is fully exposed, care being taken to bare it of axillary fat. The arm is then carried a little nearer to the side to relax the great pectoral muscle. This tendon is cut off close to the humerus (Fig. 1014). The muscle is pulled downward and inward and is loosened from the cephalic

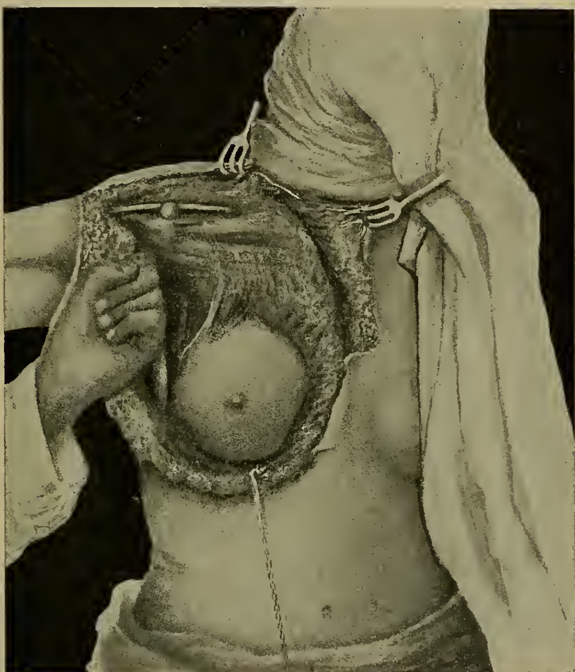

Fig. 1014.—Willy Meyer's operation for carcinoma of the breast. Insertion of pectoralis major muscle exposed. Operator's left index-finger encircling its tendon.

vein. It is then cut off near the lower border of the clavicle and the sternoclavicular articulation. It is necessary to divide the nerves that enter the pectoral muscle, and all the vessels that come into view are divided between two clamps and tied.

The next step is to divide the tendon of the lesser pectoral muscle near the coracoid process (Fig. 1015). Just beneath this tendon lies the subclavian vein. The surgeon now makes a transverse division of the fascia over the axilla, and thus exposes the axillary and subclavian veins (Fig. 1016).

Meyer's third step is to split the axillary fat over the upper portion of the latissimus dorsi up to the axillary vein, "thus dividing it from the mass of fat that enters the sulcus bicipitalis brachii."

Next, the axillary and the subclavian veins are followed up to where the subclavian passes below the clavicle, and every vessel that evidently must be

cut is divided between two ligatures and tied. This procedure saves a great amount of hemorrhage. Meyer directs us to be careful to preserve the two superior subscapular nerves, although the third subscapular must be sacrificed.

The next step in the operation is to have the assistant hold up the mass of partly loosened tissues without pulling upon them; for if he does pull upon them, Meyer truly says, he is apt to tear off pieces of periosteum or perichondrium; and such bare spots are liable to become necrotic. The surgeon now cuts to the wall of the chest, being careful not to damage the great serratus muscle. Meyer cautions us at this step to hold the blade of the knife horizontal; that is, "perpendicularly toward the thorax." "If he (the surgeon) should not thus turn the blade of his knife, but cut perpendicularly downward toward the subscapular muscle, he would enter the fat covering and enveloping the nerves and blood-vessels of this region, thus running the risk of unneces-

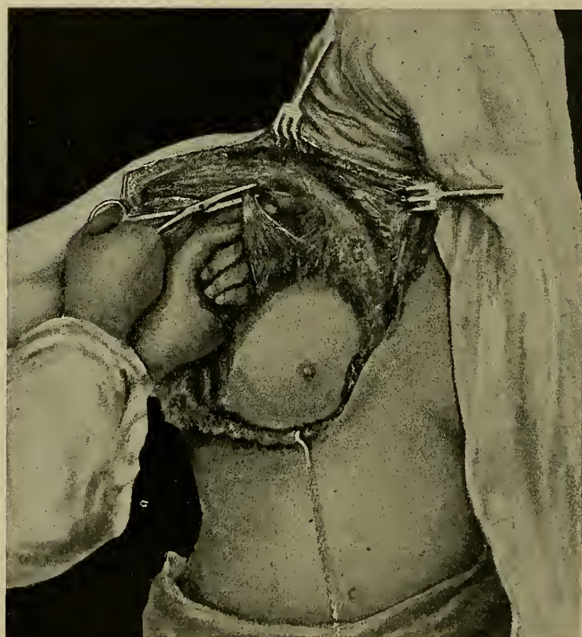

Fig. 1015.—Willy Meyer's operation for carcinoma of the breast. Finger under tendon of pectoralis minor muscle. Above, cut surface of clavicular portion of pectoralis major parallel to clavicle is visible (in the living the belly of the pectoralis major is not so thoroughly detached from that of the pectoralis minor. It is done here to show the latter's tendon).

sarily causing considerable hemorrhage and of injuring the subscapular nerves. In the general run of cases this region need not be explored; only in very advanced cases did I find a few injected glands in this area."

The pectoralis major muscle is now divided close to the wall of the chest, the cuts being parallel to the ribs, and almost level with them; and the mass being gently drawn toward the sternum. By watching carefully, one may see the perforating arteries and veins drawn out by traction before cutting them, and may usually catch each of them with two clamps and divide between the clamps. If this is impossible, they are divided and quickly picked up. The last tissue that holds the mass to the chest wall is composed of the muscle-fibers from over the sternum. These are divided close to the sternum (Fig. 1017). The final steps consist in tying all blood-vessels, draining, and suturing the wound. The draining is done through a perforation in the

posterior flap. It may be tubal or by gauze. Gauze has the advantage of restraining oozing of blood.

This operation has noteworthy merits. It can be performed far more rapidly than any other method that I have ever employed. The loss of blood is comparatively trivial, because in this operation the chief blood-vessels are divided early, are cut close to the axillary artery, and are tied. In removing the mass from the chest wall there is little bleeding, except what comes from the perforating vessels, hemorrhage from the branches of the axillary being entirely absent; and even many of these perforating vessels are tied before being *divided*. We are far less apt by this method than by the usual plan to milk lymph which contains cancer cells into the wound, or in aberrant directions through the lymphatics. As Dawbarn says, the squeezing "of the breast by the

Fig. 1016.—Willy Meyer's operation for carcinoma of the breast. Subclavian and axillary veins fully exposed. So far, glands and fat tissue not removed; smaller vessels still in connection with main trunks. Finger under fat toward sulcus bicipitalis, its nail resting on axillary vein.

retractors during its oblation, as also its handling when separated, save for its attachments to the armpit," are real dangers and may be responsible for rapid recurrence of the growth ("Annals of Surgery," March, 1908). The drain is removed in from thirty-six to forty-eight hours. The patient is placed in a sitting posture on emerging from ether and is allowed out of bed on the fourth or fifth day.

Dressing and After-treatment.—The dressing must be wide and ample. Fluffed up gauze is pushed into the axilla to obliterate the dead space and the arm is bound to the side for forty-eight hours. When the binding is removed, the extremity is placed on a pillow in a position of moderate abduction, and is abducted a little more each day. If the incision was placed well above the axillary border the mobility of the arm will be such that in two weeks the

patient can place the hand on the back of the head. Of late I have been placing the arm at once after the operation in abduction (upon a pillow or a triangular splint which rests upon the side). This is unnecessary if the incision does not run on to the arm and in front and above the anterior axillary margin. If the old incision in the axilla is used, abduction and all other plans will fail to prevent decided limitation of movement.

Inoperable Malignant Diseases of the Breast.—This term implies that a radical operation looking to cure is impossible. The conditions in which it is impossible have already been specified (see page 1438). Even if the case is judged inoperable from the radical standpoint, it may be wise to remove the mammary gland, in order to free the patient from a hideous, ulcerating area, violent pain, or harassing hemorrhage.

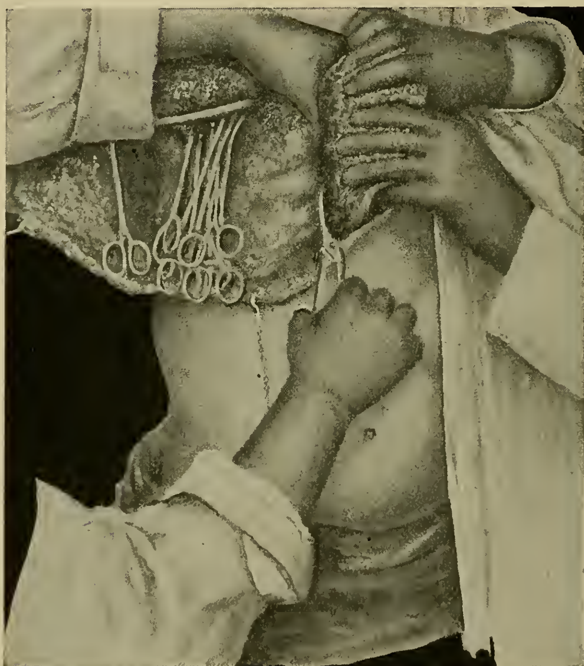

Fig. 1017.—Willy Meyer's operation for carcinoma of the breast. Pedicle of mass over sternum ready to be cut off.

It has been suggested that some cases inoperable by ordinary methods may be subjected to removal of the entire upper extremity or to disarticulation at the shoulder-joint with some prospect of cure. My own view is that when a case has advanced so far that it is not amenable to ordinary operative treatment, neither of the above-mentioned procedures offers any reasonable chance of success. If the pain is extremely violent in an inoperable case, the surgeon may relieve it by dividing the brachial plexus, or perhaps by disarticulating at the shoulder-joint.

Some inoperable cases may be greatly improved—for a time, at least—by the use of the *x*-rays; and even when the condition is not benefited in other ways, this force sometimes mitigates or greatly relieves the pain. It is said that in some cases radium is more efficient than the *x*-rays, but it is probable that most improvements by radium could have been obtained by the *x*-rays. In cases of lymphatic recurrence it is advisable to administer thyroid extract during the *x*-ray course (Woods, in "Brit. Med. Jour.," July 1, 1911).

Beatson's Operation, or Double Oöphorectomy.—It has been pointed out by Sir George Thomas Beatson that there is a certain similarity between the formation of cancer in the mammary gland and the process of lactation. In each there is an enormous production of embryonal epithelial cells; but in lactation the epithelial cells undergo fatty degeneration, and in cancer formation they do not do so, but penetrate into the tubules and the acini and infiltrate the gland structure. Beatson further points out that when a lactating cow is spayed, it continues to give milk indefinitely. This seems to indicate that removing the ovaries favors the fatty degeneration of the epithelial cells. This operation has been performed in cases of inoperable carcinoma of the breast in the hope of bringing about degeneration in the tumor mass. In the great majority of cases it fails utterly; but now and then it secures a notable improvement, and in a very few cases outward evidence of the disease disappeared, the general health improved, and there was gain in weight. The cure is apparent, but not real. The improvement is only temporary. Abbe obtained an apparent cure in 2 patients. It was at first thought that the operation would be applicable only to persons that have not passed the menopause, but one of Abbe's patients was over seventy years of age. Butlin, however, says that there is no genuine cure secured by this operation on record, and Beatson makes the same statement. The operation is not to be considered if visceral deposits exist. My own view is that the procedure offers but little prospect of success, but that, as it does offer some, the exact facts should be placed before the patient, and she should be permitted to choose whether or not she wishes the operation performed.

XL. SKIAGRAPHY OR RÖNTGENOGRAPHY (THE EMPLOYMENT OF THE X-RAYS). THE FINSEN LIGHT; BECQUEREL'S RAYS; RADIUM RAYS

The Röntgen or x-Rays.—The cathode rays were discovered by Hittorf in 1869, while passing an induction current through a vacuum tube. Crookes, of London, greatly improved the vacuum tube, and obtained a rarefaction which left in the tube but one-millionth of an atmosphere. This last-named observer found that when an interrupted current of high potential is passed through a vacuum which is nearly perfect, fluorescence takes place. In Crookes's tube the positive electrode is placed at some indifferent point, and the current from the negative electrode flows not to the positive, but directly to the wall of the tube opposite the cathode, and at this point the phosphorescent glow is detected.

In 1895 Röntgen, of Wurzburg, while making a study of cathode rays as developed in Crookes's tubes, discovered the energy which he named the x-rays. Röntgen showed that at the wall of the Crookes tube opposite the negative electrode a new and hitherto unknown energy is generated. Because of the uncertain character of this energy he gave to its manifestation the name of the x-rays or unknown rays.

The x-rays are invisible; cannot be deflected, refracted, or concentrated; are not influenced by the magnet, and produce none of the ordinarily recognized effects of heat. The rays cannot be polarized, travel with the velocity of light, and cause fluorescence in certain substances, notably in the tungstate of calcium (Edison), platinocyanid of barium (Röntgen), and the platinocyanid of potassium. They have a marvellous power of penetration. Freund ("Radium Therapy") says, "Speaking broadly, one may say that the lighter the specific gravity of a body, the more transparent is it to x-rays. On the other hand, a body's opacity for the rays increases with its density, though not in the same

proportion." "V. Novak and O. Sule, also Voller and Walter, proved that the transparency of a body to x-rays depends less upon its density than upon its atomic weight."

The x-rays in their action on photographic plates or films exhibit actinic effects. If, therefore, an object whose component parts are of unequal density—*e. g.*, the hand—is placed on a photographic plate protected from ordinary light, and exposed to the action of x-rays, the plate when developed by photographic methods will exhibit a picture of the shadows cast by the several parts of the object. Such a picture is known as a skiagraph, radiograph, or a Röntgenograph. Similar shadows will be seen on a fluorescent screen if the object is between an excited x-ray tube and the screen. The portion of the screen free from shadow glows with fluorescence. Such a screen is known as a fluoroscope or Röntgenoscope.

The real nature of the rays remains unknown. They resemble the ultraviolet and Becquerel rays in their action on a charged electroscope and in producing fluorescence in certain substances, but neither the Becquerel nor the ultraviolet rays have the penetrating power of the Röntgen rays. Many theories have been advanced. The most acceptable has been on the electromagnetic theory of light. The difference between the Röntgen rays and a beam of sodium light is said to be that the thickness of the Röntgen ray pulse is very small compared with the wave length of sodium light, and that in the Röntgen rays there is not that regular periodic character which occurs in a train of waves of constant wave length (J. J. Thompson).

Solid bodies which are struck by the x-rays emit new rays having similar properties (Saganic), known as secondary rays, and less powerful than the primary rays.

For practical purposes we may consider that the x-rays have penetrating and actinic properties.

For the production of the Röntgen rays the essential is to have an electric current pass through a Crookes tube of rather high vacuum. The state or degree of vacuum controls the nature of the rays. A tube of low vacuum will emit soft rays of low penetrating power, while the rays from a tube of high vacuum will penetrate even pure sheet lead. The vacuum of a given tube does not remain constant with use, the tendency being for the vacuum to become higher. Some get so high that they cannot be used. All modern tubes have some device by means of which the vacuum may be regulated and controlled.

The soft rays are rich in actinic value, but because of their feeble penetrating qualities are of use only in treating superficial conditions, or for the Röntgenography of thin parts, and in conditions in which much contrast of shadows is desired. On the other hand, in deep and dense parts satisfactory results can only be obtained with hard rays. In the hands of the experienced operator the quality of the rays is adapted to the condition.

To excite the Crookes tube or, as it is more commonly called, the x-ray tube it is necessary to have an electric apparatus capable of delivering a current of high tension and as far as possible unidirectional. Röntgen used the induction-coil of Ruhmkorff. The fundamental parts of an induction-coil are a primary winding, which receives and stores up the electricity from its origin or from its source of supply, an interrupter, to make and break the current, and a secondary winding, which receives the current and delivers it to a negative and a positive pole. Wires carried from these poles to their respective terminals on the x-ray will complete the circuit.

A static machine is frequently used to excite Crookes's tubes, but only the most powerful are of practical value in taking skiagraphs. The static machine is ideal for Röntgen ray therapy, for the reasons that the current is without inverse and is of high voltage, hence will operate tubes of high degrees of vac-

uum; it is a current of constant voltage, that is, it is not a wave form of current, and, therefore, all of the current is efficient; whereas all other types of apparatus give off a wave form of current, so that the voltage is comparatively low at the bottom of the wave and very high at the peak of the wave, fully half of the wave being inefficient in the operation of high vacuum tubes; and the rays from a tube of a given degree of vacuum will be more nearly homogeneous, and can be delivered to more definite purpose, if produced by a static machine. The disadvantage of the static machine is that it will not deliver a sufficient quantity of current for rapid Röntgenographic work.

The induction coil has three disadvantages: 1, its current is not always unidirectional; 2, some form of interrupter is necessary—and all forms are troublesome; 3, the output is not sufficient for rapid exposures. It is largely used for therapeutic exposures and for exciting the x-ray tube on the fluoroscopic apparatus. The current is of high voltage, though low in amperage; it is easily controlled by a rheostat and switches, and operates equally well high or low vacuum tubes. The most popular machine for diagnostic work is the transformer type, the first of which was installed in the Jefferson Hospital in 1907. This apparatus is built either for direct or alternating current. When the current supply is direct, a rotary converting motor delivers an alternating current to a high tension transformer, and at the same time drives a rotating rectifying switch, so that the waves of opposite direction are collected and delivered as a unidirectional current. When the supply is alternating current the transformer receives it direct from the line, and the rectifying switch is driven by a synchronous motor. The output of the direct current machine is limited to the capacity of the rotary converting motor, while that of the alternating current type is limited only by the amperage that may be drawn from the source of supply. With the transformer the time of Röntgenographic exposure has been reduced from minutes and fractions of a minute to seconds and fractions of a second. It is almost free from inverse current in the tube circuit, but its voltage output depends upon its amperage intake to such an extent that a tube of high penetration will only operate well when a comparatively large amount of current is delivered to it. The tube heats rapidly, and thus becomes less desirable for fluoroscopic work or for therapeutic Röntgenization. Recently devices have been made to eliminate from the tube circuit a portion of the high tension waves, so that the transformer bids fair to become of universal applicability.[1]

Physiological Effects of the Röntgen Rays.—Clinical observations have determined that in small or moderate intensity the Röntgen rays act as a

[1] A new type of x-ray tube has recently been invented by Coolidge, of Tungsten lamp fame. A detailed description of this can be found in the "Physical Review" for December, 1913. The advantage of this tube over our present standard type is that the negative electrons are furnished by a heated cathode. The temperature of this cathode determines the amount of electrons to be given off, hence the amount of x-ray energy that may be emitted from the tube.

The cathode is heated by a storage-battery having a rheostat and meter in circuit, so that the temperature of the cathode can be definitely regulated. The penetrating qualities of the Röntgen rays given off by this tube are dependent entirely upon the voltage of current furnished by the high tension transformer. A definite quantity of x-rays of a definite degree of penetration can be given for any desired length of time. Any set of conditions as to hardness of rays or amount of rays can be duplicated accurately at will.

The vacuum of this tube is at least a thousand times greater than the vacuum of our present standard tube and requires no regulation, so that there will be none of the disadvantages due to regulation of the vacuum.

Dr. Coolidge believes that he will be able to produce an x-ray tube which with adequate exciting apparatus will produce x-rays that will be fully as penetrating, if not more so, than the most penetrating gamma-rays of radium.

A great deal is to be expected from the proper use of this new type of x-ray tube in the field of therapeutics. The tube is not yet obtainable commercially.

stimulant to cell-growth and metabolism, while prolonged radiation produces cell destruction.

Histological study shows that the cellular elements of the integument are first affected, and that only after repeated or prolonged exposures are the normal connective-tissue elements acted upon noticeably.

Cell degeneration occurs and is followed by inflammatory changes in the surrounding tissues, notably in the blood-vessels.

After sufficient irradiation this process will go on to endarteritis and necrosis.

The cause of these tissue changes under x-ray exposure has been the subject of varied conjectures, viz.: liberation of ozone in the tissues (Tesla); interference with cellular nutrition caused by static electric currents "induced by the introduction of the patient's tissues into the high potential induction-field surrounding the tube" (Leonard); the destruction of the nerve supply of the tissue (Hopkins); irritation of the peripheral extremities of the sensory nerves, causing vasomotor paralysis (Rudis-Jicinsky); "no doubt there is some chemical action which causes metabolic disturbances" (Beck); "the effects of x-rays upon tissues and upon substances sensitive to x-rays are due to actinic properties of the same character as those of light" (Pusey).

It is generally admitted that the rays themselves are responsible for the tissue changes, and not some external agent, such as electric discharges.

The earliest noticeable effect of exposure to x-rays is a tanning of the skin in dark people or reddening of the skin in blondes. Ormsby has noted this analogy between the action of x-rays and the sun rays.

Glandular structures undergo atrophic changes after repeated exposures. Its action on the nervous mechanism is more difficult to understand, but that it has anodyne effects in certain painful conditions is beyond question. There is also testimony, but not certain evidence, that the x-rays have an inhibitory influence on the sympathetic nervous system. It has occurred that a small ureteral calculus, lodged in the lower end of one ureter for a long period, has passed into the bladder within a few days after x-ray examination.

The influence of Röntgen rays is in many cases distinctly inhibitory to the growth of bacteria.

The untoward effects from overexposure to the x-rays may range from falling out of the hair or slight irritation of the skin to the production of sterility, extensive sloughing, chronic non-healing and painful ulcers, cancer, and death. These effects may be acute or chronic. The patient is more apt to develop acute conditions, while the operator or investigator is constantly in danger of the remote or chronic lesions.

The so-called *x-ray burn* is not a burn, but a dermatitis or a gangrenous process. A burn results from heat, begins on the surface and at once, is accompanied by pain from the moment of its origin, and is followed by inflammation starting from the surface burnt. An x-ray burn does not come in evidence for several days or for a longer time after the application of the cause, and the inflammation begins in the skin rather than upon its surface. So called x-ray burns may be classified by stages or degrees. In a burn of the first degree (*x-ray dermatitis*) the skin is hyperemic, more or less tender, and may itch or burn, there is increased pigment formation, and the outer layer of the skin will "pull off" as in sunburn. It may develop any time after a few days, but usually does so in from ten to twenty. Such a condition is popularly known as a "reaction." No treatment is required for dermatitis of this degree, unless there is severe itching or burning, when we may use the following preparation advised by Dr. Martin F. Engman ("Interstate Med. Jour.," July, 1903): It consists of 12 drams of boric acid, 1 oz. of zinc oxid, 1 oz. of starch, 1 oz. of subnitrate of bismuth, 1 oz. of olive oil, 3 oz. of lime-water, 3 oz. of lanolin, and 12 drams of rose-water. The powder is rubbed in a mortar, the lanolin is

added. The olive oil and lime-water, mixed, are slowly added to the powder and lanolin. The mixture is stirred, the rose-water is added, and the preparation is beaten into a creamy paste. If itching is severe, 1 to 2 per cent. of carbolic acid is added. The paste is spread on several thicknesses of gauze and the gauze is covered with a rubber-dam.

In an "x-ray burn" of the second degree the condition becomes more painful, vesicles or even bullæ form, there is swelling, and if the blisters are opened the denuded cutis will weep. The raw area is sensitive to touch and to direct contact with air.

This condition requires little treatment beyond aseptic attention, the use of the above-mentioned ointment, and protection from further exposure to x-ray or air.

The "x-ray burn" of the third degree involves all the layers of the skin and more or less of the underlying tissue in a process of sloughing. The slough is white, adherent, tough, and stringy. G. G. Hopkins calls the process *white gangrene* ("Phila. Med. Jour.," Jan. 6, 1900). The pain is excruciating and constant, seeming as if "red-hot coals were held against the body." Sloughing may continue for weeks or months, and the exudate is profuse and irritating. The process may eventuate in gangrene of a large area, even of a limb. Such ulcers require months to heal, if they heal at all, and are not improved by the treatment which relieves ordinary burns. Excision with subsequent skin-grafting or amputation may be necessary. In the early stages alkaline astringents give the best results, *e. g.*, a mixture composed of 2 drams each of zinc oxid and bismuth subnitrate, $\frac{1}{2}$ fluidram each of liquor potassa and liquor plumbi subacetatis, 2 drams of glycerin, and sufficient lime-water to make 6 fluidounces.

This mixture may be applied twice daily and will relieve much of the itching and burning as well as control the exudate. It should be applied over a considerable area surrounding the seat of inflammation. It is generally taught that ointments should not be used to relieve the pain of ulceration. Leonard considers them conducive to malignant changes. Scarlet red ointment has been used by Manges in a case of non-healing ulcer of six months' duration. The results were distinctly encouraging at first, but the ulcer, being in the region of the umbilicus, was subjected to great tension by a coexisting ascites, and extended more rapidly in one direction than it healed in another. Then, too, the patient was cachectic from extensive carcinoma of the abdominal viscera.

In extensive ulceration the wound must be kept as clean as possible and free from irritants. When sloughing ceases and granulation tissue forms, mild stimulants may be applied.

The patient's general health should be improved in every possible manner.

Skin-grafting is not usually successful without excision of the floor of the ulcer, but should be tried. In spite of all treatment the condition may remain a chronic ulcer and be subject to malignant change.

Sometimes the results of an x-ray burn may be most serious. In a case reported by J. P. Tuttle it became necessary to amputate the thigh ("Med. Record," May 5, 1898).

The chronic "x-ray burn" or chronic x-ray dermatitis is seen among operators or men working more or less constantly with the rays. The onset is very insidious. Ulcers may not form for a year or more. The earliest signs of trouble are brittleness of the finger-nails and itching about the matrices. Scratches on the fingers heal sluggishly. The skin atrophies, telangiectases form, vesicles appear and disappear, keratoses develop, fall off, and return. Small ulcers start and gradually heal, reappear, become more extensive, painful, and sluggish. The finger-nails drop off, leave sensitive surfaces, and grow again indifferently or in a misshapen condition.

If exposure is continued the ulceration advances, and the tendons and even phalanges may slough away. Usually when ulceration of this kind has started, the damage is irreparable except through amputation or excision, with, of course, absolute protection from further exposure.

These lesions are most common on the hands, but may occur elsewhere.

That malignant changes take place in chronic *x*-ray lesions has been definitely shown clinically and by the microscope. Porter, of Boston, has made an extensive study of these lesions, and emphasizes the importance of both excision and skin-grafting and amputation as methods of treatment.

His results were excellent. Palliative treatment should be limited to cleanliness and care.

Sterilization of either sex by use of the *x*-ray is possible and should be guarded against.

Can the x-rays cause death? The *x*-rays do not cause death directly, but may inaugurate a lesion which eventually causes death. Death may follow a burn without being directly due to it. Carcinomata have developed in chronic *x*-ray lesions and produced death; at least 7 fatal cases from multiple carcinomata following chronic *x*-ray dermatitis are known to have occurred in the United States. Two of these cases occurred in Philadelphia, and one of them was in my charge. One of the fatal cases was from Hartford, Conn., and I was consulted by him.

Unnecessary exposure to *x*-rays is to be avoided. The operator should remain as far away from the excited tube as possible, and have between it and him a lead screen no less than $\frac{1}{4}$ inch in thickness and of dimensions sufficient to protect his entire person. The patient is to be protected from undue irradiation by means of lead-glass or lead-covered tube-holders and lead diaphragms. In the treatment of lesions beneath the skin some form of filter should be used over the exposed area. Sheet aluminum is commonly used. Pfahler has suggested the use of sole leather.

The function of the filter is to absorb the soft rays, which would be otherwise taken up by the skin and would irritate that structure. With proper care patients may be treated frequently and with perfect safety for a long time.

The Uses of the Röntgen Rays.—In the hands of trained and experienced workers this agent is a most valuable aid in nearly all branches of medicine and surgery; whereas, in the hands of the untaught and inexperienced, it may lead to grave error in diagnosis, and is, even at the present day, fraught with all the dangers of its early use. The general practitioner should not attempt its use without first having had practical training.

For diagnostic purposes studies may be made by means of the *fluoroscope* or by making Röntgenographs (skiagraphs, radiographs).

Edison's fluoroscope consists of four sides of a box, one end being open and made to fit tightly over the observer's eyes, the other end being closed with cardboard made fluorescent by smearing it with mucilage, and before the mucilage is quite dry sprinkling it with crystals of tungstate of calcium. If it is desired to examine the hand with a fluoroscope, the extremity is held opposite an excited Crookes tube and from 6 to 10 inches away from it; the end of the fluoroscope, which is covered with fluorescent paper, is placed near the surface of the hand which is away from the tube, and the observer looks through the other end of the instrument. The flesh seems but a dim haze, and the shadows of the bones are distinctly outlined. The fluoroscope is of advantage in the examination of the movable organs of the chest and abdomen. This method, except with special forms of apparatus, endangers both the patient and operator. It was used extensively in the pioneer days and caused the vast majority of injuries to the early workers. The fluoroscopic method has gained many American adherents in the last few years, owing to the development of appara-

tus which enables the Röntgenologist to work more nearly in safety. The American fluoroscopes are, as a rule, far more protective than the foreign types. Quite a few operators have apparatus built into their laboratories to suit the local conditions.

All modern fluoroscopes enable the operators to study their patients by the combined method of fluoroscopy and Röntgenography without changing the position of the patient or x-ray tube.

Röntgenographic technic has been wonderfully developed in the last few years. The method now used has the advantage of safety to patient and operator, as well as permanency of record. With the most improved apparatus a Röntgenograph of any portion of an average sized person can easily be made with an exposure of five seconds or less, so that the motion of breathing need not interfere as it did in former years. Children are skiagraphed by instantaneous exposure and seldom require an anesthetic. It is the most valuable agent we have for the study of bone conditions. In fractures the rays enable us to determine the nature of the injury, the amount of splintering, the existence of impaction, the question whether or not the fragments are in contact or can be brought in contact, the direction of the line of fracture, the variety of deformity, the existence of more than one fracture, the presence of epiphyseal separation or dislocation alone or with a fracture, the existence of an ununited fracture, the presence of callus, and if the splints are holding the fragments in apposition. By means of stereoscopic Röntgenographs fractures of any part of the skull can be detected; and the actual relations of the parts in fracture or dislocation of the hip, pelvis, or shoulder can be determined.

Fractures of the spine in the lower dorsal region are difficult to demonstrate in stout persons. In bone disease the experienced Röntgenologist can greatly aid the surgeon in making a differential diagnosis. The dissolved appearance of the bone in myeloid sarcoma without evidence of demarcation differs from the tuberculous bone, which presents a picture of impoverishment of mineral matter, but with more or less distinctly outlined foci of destruction. Bone atrophy due to pressure or disuse presents still another picture. Chronic periostitis, osteoperiostitis, necrosis, chronic osteomyelitis, and osteosclerosis cast shadows more or less characteristic. The bone changes in osteitis deformans (*Paget's disease*) are accurately differentiated. Bone-cysts, osteosarcoma, osteoma, and osteophytes show clearly. Conditions about the joints, such as arthritis deformans, ossifying bursitis, tabetic osteo-arthritis, and foreign substances within the joints, the character of deformity and whether due to disease or congenital defect can be determined. The bone changes of rickets and scurvy appear in distinguishable manner. Achondroplasia presents a picture unlike anything else.

Pathological processes in the accessory sinuses of the skull and in the mastoid cells are capable of detection, and the condition as well as position of the teeth can be shown with great clearness.

Stereoscopic Röntgenography of the head is often of very positive value in obscure intracranial lesions. Variations in the size of the pituitary body are determined by the measurement of the sella turcica. Likewise, disease of this gland or tumors in this region are shown by destruction of the floor of the sella turcica and the clinoid processes. Brain tumors which are superficial produce localized atrophy of bone by pressure on the inner table of the skull. In such cases the diagnosis is almost positive by means of Röntgenographs. Normally, the inner table of the skull is more or less indented by the convolutions of the brain. These indentations become striking in congenital syphilis, in which condition the skull sutures unite early and the bones expand less rapidly than the brain, and the ventricles dilate. This same condition develops with internal hydrocephalus from other causes, but in the latter instance the sutures

are ununited and even separated. On the other hand, in acute external hydrocephalus the sutures are separated, but the convolution markings on the internal table of the skull are absent.

In many cases of epilepsy there are hypertrophies or marked variations in size of the sella turcica, and, though the significance is not apparent, we frequently find evidence of calcareous deposit in the pineal gland from the size of a pin-head to a match-head or larger. They are usually associated with hypertrophies of the clinoids, are found occasionally in acromegalics and in cases of exophthalmic goiter, and headache or other nervous manifestations are sometimes discovered.

Intrathoracic conditions from very early tuberculous deposits in the lungs to generalized involvement; thickened pleura; effusion; cavity formation; consolidation; the excursions and relations of the diaphragm (*Williams's sign*) to fixation of this organ; from the normal heart to all sorts of variations in size, shape, and position; dilated aorta; aneurysm; the presence of enlarged mediastinal or peribronchial glands; and tumors of this region can be studied to great advantage in connection with physical and clinical findings.

Volumes have been written on the *x*-ray study of gastro-intestinal diseases. With adequate equipment as well as skill in technic and interpretation the Röntgenologist renders most efficient aid in the diagnosis.

It has become almost a matter of routine hospital practice to have an *x*-ray study of the progress of a bismuth meal in patients with gastro-intestinal symptoms. The bismuth meal consists of from 2 to 4 oz. of bismuth subcarbonate or oxychlorid suspended in a pint of buttermilk, one of the bacillated preparations of milk, or some especially prepared liquid food. "Kefir" and "fermilac" are popular in this country, for the reason that they keep the bismuth in suspension for a long time, are palatable, and are articles of diet suitable for most patients. Chemically pure barium sulphate has replaced bismuth in the good opinion of some workers. The stomach will empty a barium meal more rapidly than a bismuth meal. Bismuth subnitrate is no longer used because of the danger of nitrite poisoning. The study should be made fluoroscopically as well as by means of Röntgenographs.

The normal esophagus varies very little in different individuals, so that variations from a normal condition are due to functional disorder or disease. The stomach, however, does vary greatly in healthy individuals, and the study of this organ is complicated. We seldom find a stomach occupying the oblique position high in the abdomen, as described in medical text-books. In a very muscular, healthy person the stomach is usually more or less oblique, with the pylorus extending about 1 or 2 inches to the right of the median line and on a level, slightly above the umbilicus. The shape of this stomach is always controlled by its own power of contraction, or its resistance to expansion. The other extreme is the low, sagging, atonic stomach of the muscularly weak individual. The shape of the stomach depends upon the amount and weight of its contents. When filled, the greater curvature is several inches below the umbilicus, while the pylorus remains on a level with the umbilicus and is usually near the median line. This stomach is normal or, at least, true to the type of the individual. Generally, however, we speak of a stomach as being normally situated when the cardiac and median portions lie to the left of the median line, while the pyloric portion extends 1 inch or more to the right of the vertebral column, and when comfortably filled the pylorus is not more than 2 inches above the lowermost point of the greater curvature. Beyond this we find different degrees of ptosis or dilatation from congenital defect in support, disease, or atony. Schlessinger classifies the variations into hypertonic, orthonic, hypotonic, and atonic.

Röntgen ray examination should be preceded by chemical analysis of the

stomach contents and careful physical examination for points of tenderness, with markings on the skin to guide the Röntgenologist. The examination should be made with the patient in the erect posture, since the recumbent position is essentially a natural therapeutic measure for the relief of displacement producing symptoms.

The process of deglutition is observed on the fluoroscopic screen. Under normal conditions the bismuth mixture makes a sinuous, slowly moving shadow, and enters the pars cardiaca without hesitation, showing throughout the caliber of the esophagus. Diverticulæ will retain a portion of the bismuth meal and cast a locally enlarged shadow, smooth in outline. Pressure from without will cause a deviation of the normal line in one or more planes, but not necessarily narrow the normal width of the bismuth shadow. Functional constriction is differentiated by its regularity of outline, comparatively slight dilatation above the stricture, and a more or less sudden relaxation, permitting the meal to pass in volume. An organic stricture retains its shape, regular or irregular; the bismuth always passes in a thin stream. On the proximal side of the stricture, where the esophagus is dilated, the bismuth is retained and casts a broad shadow.

Filling of Stomach.—The normal hypertonic stomach fills slowly from cardia to pylorus. The atonic stomach receives the bismuth meal and lets it drop quickly to the most dependent portion, assuming shape only when filled. The orthotonic and hypotonic types present intermediary appearances. A Röntgenograph taken at this stage of the examination will serve as a permanent record of size, shape, and position of the stomach. The picture should be made in the erect posture with the plate on the abdominal aspect of the patient, but without pressure against the abdomen.

Fig. 1018.—Marked gastroptosis. (Taken by Dr. W. F. Manges.)

Defects in filling of the stomach are due to external pressure, adhesions to other organs, or to functional spasms, contracted scar-tissue in the stomach wall, or invasion of the stomach wall by new growth. Röntgenographs will reveal an indentation produced by the spleen, kidney, or colon; and changing the position of the patient or making pressure over the abdomen often determines the presence or absence of external adhesions, since the stomach is a more or less movable organ. Irritation of a florid ulcer by food will cause a more or less deep contraction of the transverse muscular fibers at the level of the ulcer, which contraction or indentation will last for from a few seconds to several minutes or longer.

The indentation is deeper than a normal peristaltic contraction, persists for an appreciable time, its edges are smooth, and it is opposite the area of ulcer. It can usually be reproduced by pressure over the stomach. Sometimes such a contraction persists so long as to be mistaken for an organic hour-glass contraction. It is usually associated with hyperacidity, and occurs most frequently in the middle portion of the stomach along the greater curvature; the stomach empties slowly. Contracted scar-tissue from healed ulcer will produce permanent defect in the stomach outline in extent dependent upon the amount of cicatrization. New growth invading the stomach wall will produce permanent filling defect so irregular in outline as not to be mistaken when extensive; is associated with absence of hydrochloric acid, and rapid empty-

ing of the stomach when the pylorus is not obstructed. The character of peristalsis is in itself not an important factor in diagnosis, since the type of stomach usually determines the depth of the contraction. Jonas has discovered reverse peristalsis. Haudek considers the phenomenon diagnostic of stenosis, ulcer, erosion, or carcinoma.

No less important than the filling is the emptying of the stomach. A normal stomach, that is, one that is free from disease within or obstructive influence without, except when it is of the extreme atonic type, should pass the bismuth meal above described in from three to six hours, according to the type or tone of the stomach. Conditions causing rapid emptying of the stomach are those associated with decrease in hydrochloric acid or increase in alkalinity of the duodenal secretion, and occasionally with non-closure of the pylorus. Those causing delay are, except in the extreme atonic type, associated with increased acidity or organic changes about the pylorus.

Holzknecht has arranged a number of symptoms-complex which, though condensed, are very instructive:

"Symptom-complex I: Bismuth residue after six hours. Normal stomach shadow. Achylia. Diagnosis: Small carcinoma of pylorus."

The retention is due to pyloric obstruction. If unobstructed, the presence of achylia alone would insure rapid emptying.

In symptom-complex IV he states: "Small residue after six hours. Sensitive pressure point over the stomach. Normal stomach shadow. Diagnosis: Simple gastric ulcer."

He continues: "This diagnosis is fairly certain and simple. In all cases of gastric ulcer there is always a certain amount of loss of motility. Handek has never found an ulcus ventriculi without this delay in the evacuation of the organ, and no case of spasm of the pylorus without some lesion of the stomach wall.

"As regards pressure point, it is not enough merely to find a sensitive point somewhere in the epigastrium, but we ought to demonstrate radiographically that the pressure point falls on the lesser curvature where an ulcer is most frequently situated, and that it moves with the stomach by pressure or indrawing of the stomach walls (Jonas). This complete diagnosis requires much experience both in radiology and in palpation; happily, there are a number of other symptoms which confirm the diagnosis. These are:

"1. Antiperistalsis. 2. Displacement of the pylorus upward and to the left. 3. Snail form of the lesser curvature. 4. Stabile transverse contractions. 5. Changing transverse contractions." (We would add hyperacidity.)

"Symptom-complex VII: 1. Large residue after six hours. 2. Dilatation. 3. Loss of tone. Diagnosis: Old ulcer stenosis.

"Symptom-complex VIII: 1. Large sickle-shaped residue. 2. Marked defect in filling of pars pylorica. Diagnosis: Carcinoma on base of an old ulcer, with stenosis. This picture is much more common than might be suspected. It was not known until recently that advanced stenosis of the pylorus, with dilatation and paralysis, might exist without vomiting or other severe symptoms. Vomiting may set in later, not from stenosis, but from the commencing carcinoma. The signs of dilatation and vomiting and the previous history of ulcer all point to stenosis of the pylorus, and do not in any way interfere with the indications for operation."

In addition to the above groups of symptoms depending on delay in emptying the stomach we must consider mechanical stenosis due to external adhesions. Manges has observed 2 cases, in each of which a pendulous gall-bladder filled with gall-stones was in close relation with and adherent to the pylorus. One stomach was of the orthotonic type, the other of the atonic type and more or less dilated. Both retained a portion of the bismuth meal long after six hours.

At operation, after freeing adhesions in each case, the pylorus was patulous and no evidence of organic change in the stomach wall was found by palpation. Both patients have made good recoveries, further substantiating the belief that disease of the stomach did not exist. One of the two was operated on by DaCosta, the other by Stellwagen, and the diagnosis of gall-stones in each instance was only made after incision. Pericholecystitis and perihepatitis are common conditions, and frequently involve the pylorus and first portion of the duodenum, nearly always producing more or less mechanical obstruction. Except in the case of pendulous gall-bladder, the pyloric end of the stomach, the duodenum, or both are drawn upward and to the right. The relations between these organs cannot be altered by change of posture or pressure, and there is usually tenderness. Again, delay in emptying the stomach may be caused by stricture of the duodenum from old ulcer.

The symptom of a sensitive pressure point is only of localizing value, *per se*, when a gastric ulcer has sufficient depth to produce inflammation of the peritoneum. It is always present in perforating ulcer, and is suggestive of deep ulcer when accurately traced to some definite point with relation to the stomach.

Organic hour-glass stomach is nearly always due to contracted scar-tissue the result of an old ulcer, and is usually situated in the median portion of the stomach. Carcinoma may develop secondarily, and when present usually produces more or less rapid cachexia. Marked hour-glass contraction, if non-malignant, may exist a long time without loss of weight.

Pfähler ("American Quarterly of Röntgenology," Feb., 1913) groups Röntgenological evidences of gastric ulcer under three headings, as follows:

"1. The evidence of perforation: (*a*) A projecting shadow outside the gastric shadow. (*b*) A gas bubble lying above this collection of bismuth. (*c*) Perigastric adhesions or involvement of other organs. (*d*) A palpable tumor connected with the stomach, but not affecting the lumen. (*e*) The above may be associated with either an organic or spasmodic hour-glass contraction of the stomach. (*f*) Retention of bismuth in the ulcer after the remainder of the stomach has been emptied. (*g*) Resistance corresponding to the projecting shadow.

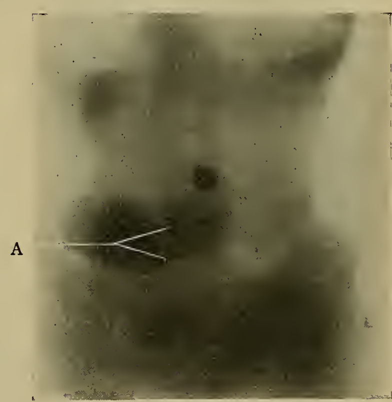

Fig. 1019.—*A*, Functional hour-glass contraction of stomach. (Taken by Dr. W. F. Manges.)

"2. The evidence of irritation, due either to a florid ulcer or to an irritable scar of an ulcer: (*a*) Spasmodic contraction. (*b*) Retention of food in the stomach after six hours. (*c*) Painful pressure point corresponding to the location of the ulcer. (*d*) Normal outline of stomach.

"3. Secondary effects usually associated with a callous ulcer: (*a*) Pyloric stenosis and gastrectasis. (*b*) Fixation. (*c*) Organic contraction—hour-glass. (*d*) Interference with peristalsis. (*e*) Reversed peristalsis. (*f*) A contracted lesser curvature with retraction of the pylorus to the left."

The diagnosis of duodenal conditions requires the Röntgenologist's best skill in technic and interpretation of both the fluorescent screen and plates. The principal findings are:

1. Rapid emptying of the stomach. This symptom is only of practical value when achylia or non-obstructive carcinoma of the stomach is absent.

2. Irregularity in outline at all times of the first portion of the duodenum,

familiarly known as "the cap." The value of this symptom depends upon the fact that the first portion of the duodenum, when not diseased, is a very constant anatomical structure. It may, however, be confused with defective outline due to result of disease in adjacent organs. In either case surgical interference is indicated.

3. The majority of duodenal ulcers occur in the first portion.

4. Dilatation of the duodenal "cap" indicates obstruction in some other portion of the duodenum.

5. Penetrating duodenal ulcer permits small projections of bismuth beyond the rest of the mass. These small portions remain for some time and occasionally contain a bubble of gas.

6. A sensitive pressure point is found in many cases to be directly over some portion of the duodenum, and when there are no external bindings the tender spot moves with the organ.

Cole's method of serial radiography of the bismuth meal is of great value in duodenal conditions. He makes twelve or more exposures in rapid succession, after the proper position of the patient has been determined fluoroscopically ("American Quarterly of Röntgenology," March, 1912). George and Gerber report only three partial errors in the Röntgen diagnosis of 59 operated cases of duodenal lesions (Ibid., June, 1913).

Fig. 1020.—Extreme ptosis of colon: *A*, Hepatic flexure; *B*, splenic flexure. (Taken by Dr. W. F. Manges.)

Adhesions and constrictions of the rest of the small intestine cause stasis of the bismuth meal and gas above points of involvement.

The colon is studied Röntgenologically after ingestion of the bismuth meal, and during and after injection of bismuth suspension per rectum. Also both in the erect and recumbent postures. The ingested meal under normal conditions will have passed through the ileocecal valve in from eight to twelve hours, and in from twenty-four to thirty-six hours will have been expelled. The injected bismuth suspension should be studied fluoroscopically. The findings are usually of a more positive nature than are those of the stomach and small intestine.

They are, briefly: The position and course of the colon. Evidence of adhesions, constrictions, and dilatation. Incompetency of the ileocecal valve (Case, "American Quarterly of Röntgenology," Nov., 1912). The obstructive effect of gas in elongated sigmoid loops (Pfähler, "Jour. Amer. Med. Assoc.," Nov. 16, 1912). The presence of impacted feces. The extent of motility of the different portions of the colon; the presence and extent of congenital dilatation. And often the location and extent of malignancy.

Frequently more than one examination is necessary before attempting a diagnosis. It is not essential to purge prior to examination of the ingested meal, but the colon should be thoroughly emptied by irrigation before injection. Sedative suppositories may be used before injection if the rectum is very irritable, and the temperature of the bismuth mixture should be a little above that of the body.

In a study of the urinary organs the Röntgenologist should be able to determine the size and position of the kidneys in a normal subject weighing 160 pounds or less. In larger persons only the best skiagraphs will show the outline of the kidneys. In patients under 160 pounds renal calculi from the size

of a No. 2 shot to the largest found, whether single or multiple, in one kidney or both, and relatively their situation in the kidneys (except in stones composed of pure uric acid) can be determined in Röntgenographs of the best quality.

Ureteral calculi are subject to the same display as renal calculi. The course of the ureters is by no means constant, so that one cannot say that a shadow lies in the line of the ureter unless this line is determined by additional means. However, in the great majority of instances the history of renal colic; a point of tenderness on deep pressure; the presence of microscopical quantities of blood in the urine; the fact that ureteral calculi are almost never round, but oval or irregular, in contrast to the small round shadows cast by phleboliths, or calcareous deposits in the mucous membrane of the female genitalia; and, the mulberry appearance of calcified lymphatic glands, are sufficient to confirm a Röntgenographic diagnosis of ureteral calculus. Vesical calculi are more apt to escape notice since they are not infrequently composed entirely of uric acid. When they do contain more dense material the Röntgen diagnosis is usually positive as to size and number.

In the past few years great progress has been made in the Röntgenographic study of surgical conditions of the urinary organs with the aid of ureteral catheterization and injection of solution of colloidal silver. The study demands the assistance of one skilled in the use of the ureteral catheter, and this part of the subject is treated of in another section (see page 1301).

The part of the Röntgenologist is, to be prepared to make Röntgenographs at intervals during the injection and with the patient in both the recumbent and erect postures when desired.

The points of information gained by the Röntgen study of the kidney pelvis injected with collargol (*pyelography*) are: the position, shape, size, and the extent of mobility; also the relation of the kidney pelvis to calculi in the kidney, ureter, or gall-bladder.

The normal kidney pelvis will hold from 10 to 30 c.c. of the solution, and the calices are sharp in outline, branching at the apices, and well separated. The hydronephrotic kidney may hold any amount above this to 500 c.c. or more. The calices are less separated, the apices are rounded and smooth, and all the calices have much the same appearance. The pyonephrotic kidney may hold small or large quantities; one or more of the calices may be involved, and the outline is irregular, never smooth, as in hydronephrosis. Tumors involving the kidney produce distortion, but usually not marked enlargement of the pelvis and calices. One or more of the calices may be long, narrow, and irregular in outline. Abscess of the kidney when communicating with the renal pelvis permits of injection with collargol solution, and shows as a more or less large shadow external to the shadow of the renal pelvis.

The mobility of the kidney may be shown in some cases by skiagraphing the injected kidney before and after manual displacement of the organ, but when possible the exposures should be made with the patient recumbent one instant and erect the next. The change must be made quickly, as the collargol promptly leaves the unobstructed pelvis. A stone in any portion of the kidney pelvis will be included in the shadow of the injected pelvis; a point which not only serves to differentiate stone in the pelvis from stone external to the pelvis, but shows the necessity of preliminary Röntgen examination.

The study of the ureters by this method requires that the ureters be filled to their maximum capacity throughout their entire length at the time of exposure. The patient may be placed in the Trendelenburg position with the ureteral catheter inserted only a few centimeters, so that gravity will retain the collargol solution in the ureter and kidney. In this way the true line of the ureter and diameter of the lumen will be shown. In a case of hydronephrosis, due to ureteral kink associated with a movable kidney, to pressure

from without, constriction by adhesions, or obstruction within the ureter, there will be shown a dilated ureter above the impediment and a narrow lumen below. If there is more than one point of interference the ureter will show a corresponding number of areas of dilatation. An almost completely obstructed ureter will be evident by the presence of only small areas of collargol shadow above the point of obstruction. Here again, as pointed out by Fowler and Stover ("American Quarterly of Röntgenology," Aug., 1912), skiagraphing the patient very promptly after putting him in the erect posture will often show the nature of the kink. Stone in the ureter may be positively diagnosticated by finding that collargol will enter the diverticulum occupied by the stone; more or less distortion of the line of the ureter at this point and dilatation above, if the stone has been there for some time and caused obstruction. A stone acting as a "ball valve" in the ureter will be associated with dilatation including the stone shadow.

Kelly has used a water suspension of small quantities of bismuth subnitrate injected into the bladder and stereo-Röntgenographs to show the presence of and extent of tumors involving the bladder.

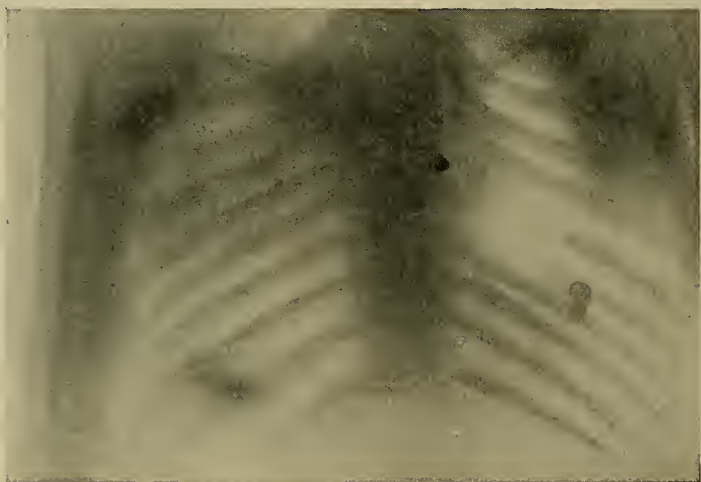

Fig. 1021.—Gunshot-wound of the lung. Rib resection for secondary hemorrhage into the pleural sac ten days after the injury; bullet not removed. Hemorrhage arrested by packing with gauze. Skiagraph taken three months afterward shows the bullet (author's case).

In addition to the above pathological findings, all sorts of anomalies and anatomical peculiarities of the urinary organs are plainly shown. Kelly and Lewis prefer an emulstion of silver iodid to collargol for pyelographic study, but the latter is more generally used.

The ureteral catheter containing lead shows the course of the ureter less accurately than proper injection of collargol, but does have the advantage of always being there at the time of exposure.

The proper preparation of the patient is an essential requirement in any x-ray study of the urinary organs. This consists of thorough purgation and abstinence from food or drink for at least six hours prior to the examination.

The liver and spleen offer but a small field for useful study. Enlargement may be seen. Biliary calculi are not often seen in the x-ray negative, because they are lacking in density and are surrounded by thick structures. One cannot make a negative diagnosis of biliary calculus by means of the x-ray.

Chronic discharging sinuses may be outlined and studied after they have been injected with bismuth paste. This study is best made by means of stereo-

scopic negatives. In advanced atheroma the outlines of the arteries of the extremities are seen in the Röntgenograph.

Localization of Foreign Bodies.—Metallic bodies, such as bullets, pieces of steel or iron, coins, pins, needles, tin, zinc, brass, etc., can be detected in any portion of the body and accurately localized. Fragments of stone, granite, marble, and lead-glass can be skiagraphed except when very small and deeply situated. Drainage-tubes and iodoform gauze can be found if lost in a sinus or cavity. Anthracite coal, glass other than lead-glass, or splinters of wood are difficult to detect unless they are of considerable thickness, are not superimposed by bone, and are embedded in thin structures so that the foreign body can be brought close to the sensitive plate. When the fingers are the seat of injury, anteroposterior and lateral views are sufficient. When in the esophagus, trachea, or bronchi the fluoroscope should be used for differentiation, after which a Röntgenograph will assist.

Foreign bodies elsewhere should be localized. If near a joint or in close relation to some surgical guide, localization is accomplished by stereoscopic

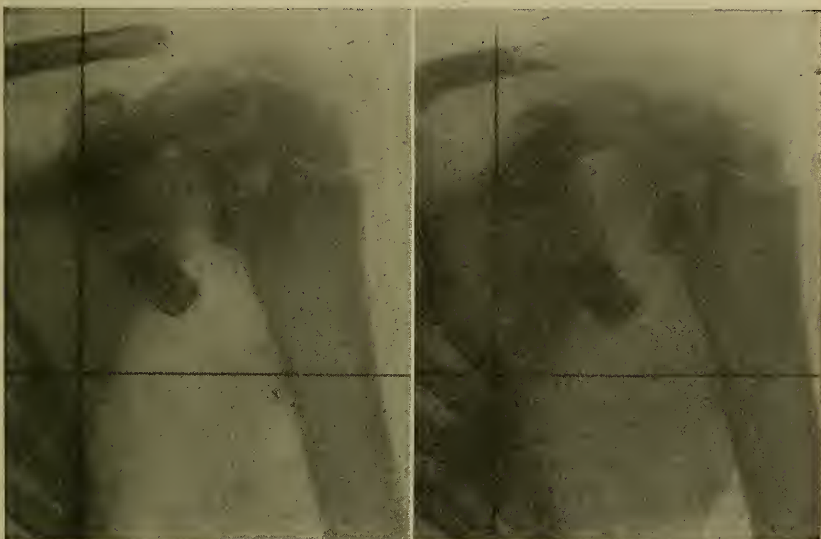

Fig. 1022.—Bullet localized by means of stereoscope. Removed by author.

Röntgenographs. (See stereoscopic skiagraph, Fig. 1022, of bullet in a shoulder case of mine. The bullet lay in close relation to the anterior surface of the glenoid margin, and on a line perpendicularly below the coracoid process. This bullet was removed with ease.)

Pieces of needle in the palm of the hand or soft parts near the surface are best localized stereoscopically when a definite relation between some known surface mark and the foreign body can be determined. A thin coating of bismuth on the palm of the hand will cause every line in the skin to show on the Röntgenograph. When the foreign body is deeply situated and not in close relation to a surgical guide, some method of localization must be used to indicate the depth and direction from a known point on the surface in which the body lies. All localizing methods are based upon displacement of the foreign body shadow by making two or more exposures with the x-ray tube in different and known positions, while the part containing the foreign body and sensitive plate remain in one position. This has been called the triangulation method.

Mackenzie-Davidson first used the cross-threads, from the known positions

of the focus point of the x-ray tube to their respective shadows on the negative, the crossing of the threads representing the position of the foreign body in relation to the sensitive plate and focus tube. Measurements were then made from some point on the skin of the patient that had registered with a known position on the negative. The Röntgenologist could then say that the foreign body lay perpendicularly beneath a certain point to a definite depth. Nearly all the modern localizing schemes are modifications of this general plan, and differ mainly in the manner of determining the position of the focus point of the x-ray tube.

A foreign body, unless it be large, may easily lie to one side of an imaginary line as drawn by the scalpel to the depth of 2 or more inches; again, a change in position of the patient will alter the relation of the foreign body to a perpendicular line from the indicated surface point. A modification of the Mackenzie-Davidson scheme was devised by Sweet. Manges improved the apparatus by

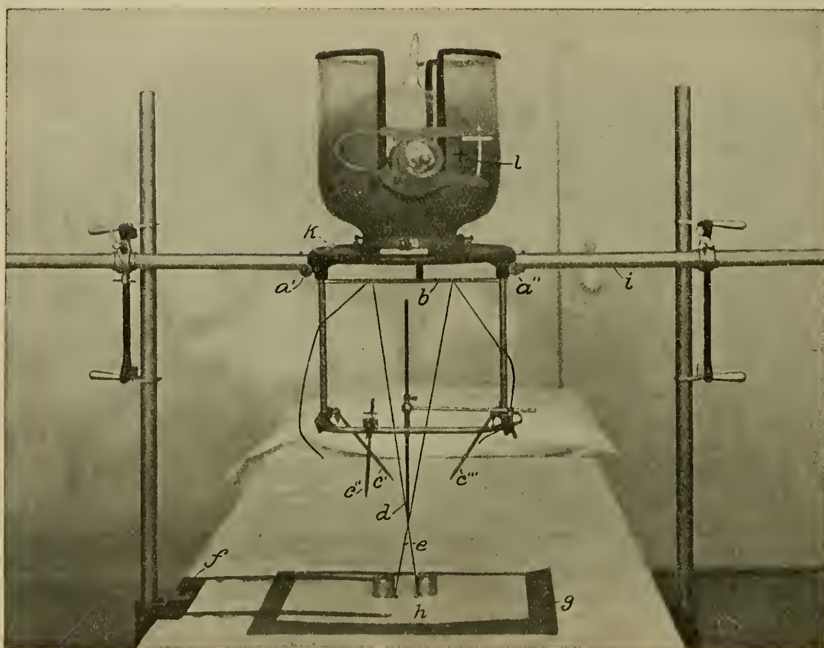

Fig. 1023.—Manges's modified Mackenzie-Davidson localizer.

limiting the possibility of error. He uses the apparatus as a guide during the surgical operation. With this apparatus all relations between the patient, foreign body, source of x-rays, and sensitive plate are obtained, maintained, and regained with ease and mechanical accuracy.

The localizer is a detachable part of the tube carriage of the Röntgenographic table, and consists of a metal frame having two upright bars (a', a''), connected near their top by a horizontal bar (b) and at the bottom by a curved bar. The upper bar is deeply notched to a scale of inches on each side of its center. To the curved bar are attached four adjustable clamps and rods, three of which (c', c'', c''') are used to establish a relation between the localizer and the patient, the fourth (d) to indicate the depth and direction of the foreign body. The fourth rod can be moved through a sleeve in the direction of its long axis, and can be held at the desired depth by a collar and set-screw attachment. The horizontal bar of the tube carriage is graduated

on one side to correspond with the notches on the cross-bar of the localizer. The focus point on the target of the tube (the source of the rays) is accurately determined by sighting from cross-lines on one side of the lead-glass tube shield to cross-lines on the opposite of the shield (*l*), and is exactly 6 inches above the level of the notched bar of the localizer. The relation between the focus point and the sensitive plate is obtained by means of a clamp on the edge of the table (*f*). This clamp has two flat metallic arms projecting over the sensitive plate and a fixed rod externally, against which the upright bar of the carriage rests.

In making the localization the patient is placed on the table as if for surgical operation. A sensitive plate, 10 by 12 or 11 by 14 inches (*g*), is put under the part containing the foreign body, the tube clamp applied, and the tube carriage, localizer, and tube are adjusted and leveled. Three of the adjustable rods of

Fig. 1024.—Bullet localized by method described in the text. Removed by author.

the localizer are made to touch the surface of the patient at as widely separated points as possible, in which positions they are tightly clamped. These three spots are touched with silver nitrate.

After all adjustments are examined, and the height of the tube from the plate noted, the carriage cross-bar is elevated and the localizer removed. By lowering the tube-carrier to 6 inches below its original position, the focus point of the tube will be at the level formerly occupied by the cross-bar of the localizer, and if the carriage cross-bar (*i*) is shifted to a definite distance to one side of zero, the focus-point will be in the corresponding position held before by a notch on the cross-bar of the localizer. After carefully adjusting the tube-holder an exposure is made. The carriage is then shifted to the opposite side of zero in the same extent and manner and a second exposure made. The patient is removed, the plate developed, and tracings of the shadows of the foreign body and arms of the table clamp made on paper. This tracing is

taken to the table and put in relation with the table clamp (*h*). The localizer is then made to occupy its original position, and threads are carried from the notches on its cross-bar to the tracings of the foreign-body shadows (*e*). At the crossing of these threads is the position of the foreign body in relation to the localizer. The point of the fourth adjustable rod can be made to touch the cross-threads from any direction (*d*). If the Röntgenologist cannot determine the best direction for incision, he may consult the surgeon, and when this is known, the point of the rod is made to touch the crossing of the threads, and its collar and set-screw fixed.

At the operation for removal of the foreign body the localizer is sterilized and applied to the patient, preferably by the Röntgenologist, if he has had sufficient surgical training to render his assistance of value from the standpoint of surgical technic; or he may thoroughly instruct the surgeon in the manipulation of the apparatus. The following precautions are to be observed: First, the localizer must be handled carefully to prevent displacement of the rods; and second, the patient should be placed on the operating table in about the position he occupied on the Röntgenographic table, so that the three marked spots on the skin receive the three fixed points of the localizer. With the apparatus in position, the indicating rod is placed in its carrier or sleeve, and when its point touches the skin the long axis of the rod indicates the direction of *incision,* while the distance between the collar on the rod and the sleeve shows the depth at which the foreign body lies. During the course of the operation the localizer should be repeatedly applied, so that excessive manipulation of the tissues may be avoided.

Manges combined the localizing process above described with stereo-Röntgenography, and devised an accurate method of measuring the diameters of the female pelvis.

The determination of the localization of pieces of metal, glass, or other substances in the eye or immediately adjacent structures by means of the Röntgen rays requires that the shadow of the foreign body, as shown on the radiograph, be studied in relation to the shadow of one or more opaque objects of known position. Dr. William M. Sweet has designed a localizing apparatus which consists of two ball-pointed indicating rods, one opposite the center of the cornea and the other situated at a known distance from the first to the temporal side. The patient is placed recumbent, with the photographic plate to the side of the head corresponding with the injured eye. Two negatives are made, one with the tube horizontal or nearly so with the plane of the two indicating rods, and the other at any distance below this plane. A special chart is employed, containing a section of the normal adult eyeball, and lines are drawn indicating the planes of shadow at the two exposures. Where these planes cross is the position of the foreign body in relation to the structures of the eyeball and orbit.

The accuracy of this method of localization has been fully demonstrated by its author and other *x*-ray workers, but the learner finds so much difficulty in understanding the lines to be drawn upon the chart to represent the planes of shadow at the two exposures, that Dr. Sweet has recently designed an entirely new apparatus, in which a single indicator is employed. As shown in the illustration (Fig. 1025) the tube-holder, indicating-ball, and plate-holder are upon a movable stage, and the tube is in a fixed carrier, so that the angle of the rays with the eyeball and the distance of the tube from the plate are always the same. A telescope and reflecting mirror permit the observer to adjust the instrument until the image of a cross-wire in the tube is in direct contact with the lateral image of the summit of the cornea. After this adjustment is made, the indicating-ball is exactly 10 milimeters from the center of the cornea.

The patient fixes with the good eye upon a circular mirror placed 12 inches above the injured eye, so that there is no movement of the eye during exposure, and the visual line of the injured eye is parallel with the plate. The two exposures are made upon one plate, one with the tube in the zero position of the apparatus, so that the rays pass in a direction corresponding with the horizontal plane of the eyeball; and the second exposure with the tube at its farthest point on the graduated rod to the right or left of the first position, depending upon which eye is to be examined. Two metal shutters are used to uncover any desired portion of the photographic plate.

Since the relative position of the tube in reference to the indicating-ball and the photographic plate remains fixed and known, the direction of the rays in passing through the eyeball follows a definite course, which is the same for the two separate exposures. Lines have, therefore, been drawn upon the localizing chart to indicate the direction of the rays at the two exposures, each line

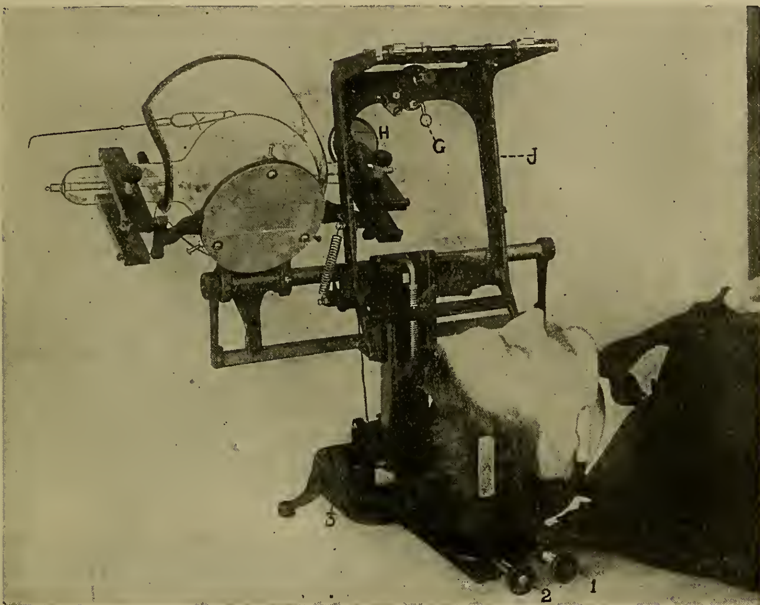

Fig. 1025.—Sweet's apparatus for locating foreign bodies in the eyeball and orbit.[1]

having the required amount of divergence to represent rays coming from a point the distance of the tube from the photographic plate. After development the photographic plate is placed in a frame containing cross-lines indicating the focal coördinates of the rays. The radiograph is moved until the shadow of the indicating-ball is in apposition with a spot representing the indicating-ball on the key-plate. A reading is then made of both the vertical and horizontal coördinate lines which pass through the shadow of the body on the radiograph, and this is transferred to the corresponding lines on the localization chart. Three readings are taken, and after having been transferred to the chart, the point of crossing of the several lines indicates the location of the foreign body in the eyeball or orbit.

The accuracy of the localization depends entirely upon the care with which the operator adjusts the indicating-ball opposite the center of the cornea and at a definite and fixed distance from it. After the exposure is made and the plate developed, the determination of the situation of the foreign body is

[1] "Transactions of the American Ophthalmological Society," 1909.

simply a question of reading from a key-plate and transferring these readings to a localization chart.

The x-Rays in the Treatment of Diseases.—It may be said that the beneficial results obtained by the use of the x-rays is in direct proportion to the skill of the Röntgenologist. No two Crookes's tubes are alike in their behavior; they vary widely from day to day, and even during one operation.

Unfortunately, there is no accurate method of computing dosage either in quality or quantity.[1] The quality of rays may be fairly well estimated by determining the electric resistance the tube manifests. Tubes of high vacuum offer great resistance to the passage of the electric current and emit hard or highly penetrating rays, while tubes of lower vacuum offer less resistance and emit softer rays. The quantity of a certain quality of rays may be roughly estimated by the amount of current passing through a tube of known vacuum in a definite period of time. The instrument commonly used in this country for this purpose is known as the milliamperemeter, the standard of measurement of electric units. In Europe the physiochemical properties of the rays are more in vogue as a means of measurement of dosage. In the United States most Röntgenologists give repeated short exposures, while abroad the tendency is to use infrequent but powerful applications of the rays.

In any case, ability gained by experience is essential for the proper selection and control of the Crookes tube in the treatment of a given condition.

The effects of x-rays which offer possibilities of therapeutic application are, according to Pusey, as follows ("The Röntgen Rays in Therapeutics and Diagnosis," Pusey-Caldwell): "(1) Their effect in causing atrophy of the appendages of the skin; (2) their destructive action upon organisms in living tissues; (3) their stimulative action upon the metabolism of tissues; (4) their power of destroying certain pathological tissues; (5) their anodyne effect." A qualitative generalization may be made, *i. e.*, superficial diseases should be treated in most instances with tubes of low vacuum, while deeper-seated lesions should be exposed to the rays from tubes of higher vacuum. Quantitatively, for causing atrophy of the skin appendages, stimulating action upon metabolism, and for the relief of pain in other than malignant conditions, mild applications or short exposures should be given; on the other hand, for destructive action maximum exposures are demanded.

In diseases of the skin the surrounding healthy parts are to be protected from the action of the rays by means of sheet-lead, while the diseased portion is directly exposed. In treating lesions beneath the surface it may be necessary to expose an area beyond the evident limits of the disease, but all overlying healthy skin must be protected from the non-penetrating rays by a filter of aluminum or leather.

Because of the possible untoward effects of exposure to x-rays, diseased conditions amenable to other forms of treatment should not be treated by the rays until after the simpler treatment has failed. In such conditions the rays are the "last resort." It is strikingly true, however, that the most signal results of x-ray therapy are obtained in conditions that are frequently incurable by other means. Many of the chronic diseases of the skin that yield but slowly to medication may be found to be safely and promptly amenable to x-ray treatment. Among these diseases are acne, eczema, lupus vulgaris, lupus erythematosis, psoriasis, and mycosis fungoides. The treatment is also beneficial in tinea tonsurans, favus, sycosis, alopecia areata, hypertrichosis, and prurigo.

In the treatment of malignant growths the Röntgen rays find their greatest field of therapeutic usefulness. With improved technic, permitting of massive doses of the rays with safety to overlying and adjacent healthy tissue, the results are far more favorable than in the earlier x-ray days.

[1] See foot-note on page 1449.

In superficial epithelioma, rodent ulcer, and Marjolin's ulcer, without glandular involvement, cure is the rule, recurrence is becoming less frequent and is amenable to cure, and the cosmetic effect is good.

When deeper structures are invaded by carcinoma cure becomes less frequent and recurrence more frequent in direct proportion to the depth of the lesion and the degree of glandular involvement. Even in advanced cases, however, for instance, when the entire contents of an orbit are involved, large portions of the nasal structure destroyed, or extensive areas of subcutaneous tissue the seat of foul and painful ulceration, and where operative interference is contra-indicated, the x-rays relieve pain and decrease discharge. Some reach such a stage of improvement that surgical procedure may be instituted with hope of success, and in a few actual cures result from x-ray treatment alone.

Epitheliomata involving mucous membranes, particularly of the lower lip, anus, or vagina, should not be treated by x-ray until after surgical methods have been exhausted. The rays are used to prevent recurrence after operation. The reason why the rays should be regarded as a last resource in these cases is that mucous membrane is very susceptible to the action of the rays and is as apt to be destroyed as is the cancer. Further, in the lower lip, glandular involvement is almost sure to exist. All forms of carcinoma with glandular involvement, if operable, should be subjected to radical surgical extirpation, and the rays should be used as a prophylactic measure against recurrence.

All cases of primary inoperable carcinoma, regardless of situation, extent, or the reason for being inoperable, should be exposed to vigorous irradiation. Likewise, all recurrences after operative procedure is prohibited ought to be afforded the possible benefits of x-ray treatment.

In sarcoma also the results are becoming more favorable, but this form of treatment is by no means on such a basis of hope that it should be allowed to interfere with or supersede surgical methods. It is a fact, however, that in some cases in which operation was not agreed to by the patient or parents, or in which the condition was deemed by the surgeon to be inoperable, surprising results have been obtained with the Röntgen rays alone or in connection with the use of Coley's toxins. I know of a case of rapidly growing periosteal sarcoma of the humerus in a young girl, the onset of which was so rapid that the mass was considered to be a subperiosteal abscess, but which was proved by x-ray examination and later by incision to be sarcoma. It was treated at first by x-rays and Coley's toxins, and later by x-rays alone. It has remained well for eighteen months. The arm is strong and useful, and the girl is robust. At the site of origin there remains a spur of bone which is about 1 inch in length, $\frac{1}{2}$ inch in thickness, and has a density equal to that of the densest portion of the humerus. Isolated cases of inoperable retroperitoneal sarcoma, fibrosarcoma of the uterus, and other deep-seated tumors, clinically or after exploratory operation considered sarcomata, have been reported as greatly benefited, controlled, or cured.

Good results in x-ray treatment of inoperable malignancies can be obtained only by the best apparatus. In the deep-seated growths hard, penetrating rays in maximum quantity are demanded. The treatment must extend over a period of months, so that great care and skill are required. There is little reason to believe that x-rays cause metastatic involvement in other parts.

The rays have been extensively used in European countries in the treatment of selected cases of uterine myomata and menorrhagic conditions.

The indications for this plan of treatment usually mean contra-indications for surgical procedures. The results, as reported by Hainisch, Runge, Bordier, and others, are very satisfactory in cases during or near the menopause. The

hemorrhage is stopped and fibroid tumors diminish or disappear. Atrophic changes occur in the ovaries and the menopause is terminated promptly. In women under forty years of age good results are not constant.

Tuberculous sinuses that are not deep seated are frequently quickly benefited, and old tuberculous glands in which ulceration has recurred after operation should always receive the *x*-ray treatment, as some remarkable results have been obtained.

Of late years exophthalmic goiter has been treated more or less successfully by Röntgen rays. The rays are of distinct value in many cases that are not operable or amenable to other forms of treatment. The Mayos use the rays for a time befure operating. Many of the distressing nervous symptoms may be relieved, the pulse-rate is often materially lowered, and changes favorable to future operation take place in the gland and its capsule. Dr. Manges, the Röntgenologist at Jefferson College Hospital, in an extreme case of exophthalmic goiter, obtained a remarkably good result from *x*-ray treatment, so far as relief of the nervous symptoms, tachycardia, and improvement of the general health of the patient are concerned. There is not a marked diminution in the size of the goiter, but the exophthalmus is distinctly less. The patient has been following for nearly four years and without inconvenience her occupation as a weaver.

Here again more data is to be desired before other methods of treating this disease, especially surgery, are to be replaced by Röntgenization. These rays are perhaps the most valuable therapeutic agent we have in the treatment of myelogenic or splenomedullary leukemia and lymphatic leukemia. Since Senn's report some years ago this plan of treatment has been widely used in connection with other remedies. A spleen of enormous size will sometimes go back to normal, high leukocyte counts may disappear, red cells and hemoglobin may increase, and the general health of the patient is apt to improve. Stengel and Pancoast have improved the technic of *x*-ray treatment in their systematic exposures of the bony skeleton, particularly the long bones, with comparatively little irradiation of the spleen until late in the course of treatment. Even very advanced cases are apt to improve greatly for a time, but even in the early cases recurrence usually appears sooner or later, and becomes less responsive to treatment. Life may be prolonged for many years, but permanent cure is very rare, if it ever occurs.

Chronic suppurating sinuses sometimes heal under the influence of these rays, and varicose ulcers are benefited by moderate exposures. The pain in rheumatic affections and neuralgias is often greatly relieved.

THE FINSEN LIGHT

It is known that below the spectrum of red light are heat rays, and above the spectrum of violet light are short violet, actinic, or chemical rays. The short violet, with the indigo rays and blue rays, constitute the Finsen light. Ultraviolet rays cause an electrified body to discharge, excite fluorescence in certain substances, affect a photographic plate, and are bactericidal, but have little power of penetrating tissues and, it is said, do not inflame tissues. Ultraviolet rays pass readily through rock salt or ice, which will not transmit heat-rays.

Finsen taught us to use these rays therapeutically. He first obtained the rays from sunlight, intercepting the heat-rays by ice or rock crystal. Later he obtained them from the arc light.

Blood in part prevents the passage of the Finsen light, hence in using the light we must make the area on which the rays are to act nearly bloodless. This is done by pressing firmly upon the part with a rock crystal through

which water passes. The rays pass through the crystal and the water absorbs the heat-rays. The rays are especially serviceable in lupus.

BECQUEREL'S RAYS

Becquerel discovered in 1896 that uranium and some of its compounds give off a radiation similar to but much weaker than the x-rays. Among these radiant substances are pitchblende, radium, and uranium. These rays are luminous, actinic, and skiagraphic (McFarland), and may produce, by prolonged action, dermatitis similar to x-ray dermatitis.

RADIUM RAYS

Monsieur and Madame Currie, after prolonged research, found that thorium and certain ores of thorium and uranium (pitchblende) are radio-active, pitchblende being more strongly so than uranium itself. The conclusion was that pitchblende contained a strongly radio-active element and that it was not uranium. In 1903 they discovered the sources of radio-activity to be two hitherto unknown elements, radium and polonium (Dawson Turner, in "Brit. Med. Jour.," Dec. 12, 1903).

Turner (Ibid.) tells us that radium gives off a radio-active emanation and three kinds of rays (alpha-rays, beta-rays, and gamma-rays). It also emits heat, and is itself at a higher temperature than the medium in which it rests. The emanation from radium is a luminous gas, which can be condensed by great cold, and which imparts radio-activity to certain bodies. It is to this gas that most of the curative effects of radium can be attributed.

Alpha-rays consist of a stream of positively charged gaseous particles. Turner points out that these particles are each about twice the size of a hydrogen atom, travel at a velocity of 20,000 miles a second, and have little power of penetration. In fact, the penetrating power of the alpha-rays is so slight that they do not pass through the glass of a tube (Robert Abbe, in "Med. Record," Oct. 12, 1907). The beta-rays consist of particles each being one one-thousandth the size of a hydrogen atom and being strongly actinic. These rays are said by Turner to resemble cathode rays and to be far more penetrating than alpha-rays. Gamma-rays resemble x-rays and have great penetrating power (Dawson Turner, Loc. cit.). According to Abbe ("N. Y. Med. Jour.," Feb. 10, 1912), the soft beta-rays and the alpha-rays irritate and stimulate; the hard beta-rays and gamma-rays destroy. It is probable that radium also generates or helps to generate a gas called helium, which has no action on tissues.

The actions of radium are extraordinary. A man entirely blind cannot perceive light when radium is brought near him, but one not quite but almost blind can, and one quite blind to form but with retention of some light perception can actually see the shapes of objects near a screen rendered luminous by radium. Turner tells us that a man retaining vision, who covers his eyes, can detect radium held in a box behind his head. If dry seeds before planting are exposed to radium rays sprouting will be retarded in proportion to the time of exposure. When meal worms are exposed to the rays "they go on living as meal worms, 'veritable Methuselahs,' as it has been said, while their sisters and brothers, unradiumized, progress for generations, completing several cycles of beetles, eggs, meal worms, etc." (Abbe, in "Med. Record," Oct. 12, 1907). Radium rays are germicidal, but act very slowly and feebly. Skiagraphs can be taken with the rays. Water and other materials may be rendered radio-active by exposure to radium rays. Probably certain natural waters have subtle powers due to radio-activity. On the tissues radium may

act to produce a retrogressive effect; may increase self-digestion; may cause irritation and inflammation, and so block blood-vessels. Severe reaction may result in ulceration. On a tumor radium produces inflammation, first of the fibrous stroma, then of the tumor-cells, or a primary necrosis (Sticker, in "Presse Médicale," May 18, 1912). It seems to have a selective action on cancerous tissue. Sometimes a spreading eruption, like that of scarlet fever, follows overaction. Abbe says that when an ulcerated surface is treated or when a tube of radium is inserted in a wound for twenty-four hours, a "specific toxemia" frequently arises. "The symptoms will be headache, chill, general aching, coated tongue, fever up to from 103° to 106° F., and an occasional rash-like scarlatina." Some hold that radium acts similarly to the *x*-rays and that the *x*-rays can do anything radium can do. Other observers believe that the radium rays have a specific action and can accomplish some few things impossible to the *x*-rays.

Radium therapy is commanding profound and widespread public interest. How real its claims are and how great its future is to be we can only guess. Sir Frederick Treves bids us be cautious in our estimates, although he thinks there may be a great future for radium therapy in surgery ("Brit. Med. Jour.," Jan. 30, 1909). It has cured many *surface* carcinomata and sarcomata, keloids, angeiomata, moles, pigmented moles, and warts. It is particularly valuable in lesions about the face when it is desirable to avoid scars; in lesions of the nostril, mouth, and other cavities. It has a very powerful action on angeiomata. So far radium has been used chiefly for inoperable cancer. It has been used most advantageously for epithelioma of the eyelid (see the striking cases reported by Abbe, in "Med. Record," Oct. 12, 1907). When treating a surface lesion the rays are obtained from radium bromid, which material is kept in a hermetically sealed platinum or lead tube. In a deep-seated tumor an incision may be made and a tube of radium bromid be inserted in the wound and allowed to remain for forty-eight hours. Attempts are being made to treat internal conditions by the inhalation of radium emanations or by the administration of materials which have been rendered radio-active and contain, so to speak, radium emanations in solution. Radio-active water has been tried for cancer of the stomach. Treatment by radium is called radium therapy; treatment by radioactive substances, radiotherapy. It is extraordinary how even very brief applications of radium may be followed by notable changes. In one of Abbe's cases an epithelioma of the forehead disappeared after one exposure of an hour's duration. Another on the side of the nose disappeared in four weeks after one exposure of an hour's duration. A cancer involving one-third of the upper eyelid entirely disappeared in two weeks after three five-minute exposures. After an exposure no changes are apparent for several days or a week. The skin at the site of application then begins to burn and itch and becomes reddened. The irritation endures for about two weeks.

Confusion has arisen because of the varying strengths and amounts used by different operators. Bromid of radium is the salt usually employed. Abbe takes as a standard 10 mg. of bromid of radium and tests other specimens by this. He calls the 10 mg. of strong German bromid of radium "the working unit." In malignant disease the best results have followed one hour's exhibition of the "working unit" to small growths and three or four hours to large growths, "with an interval of one month for study of the effect" (Abbe, Ibid.). Ischemia favors powerful action of radium rays.

In order to obtain the best results from radium heavy "doses" seem to be necessary, and heavy "doses" are very apt to burn the skin. The penetrating rays are the gamma-rays, and in order to make them reach a deep growth in sufficient intensity to do good the superficial parts are endangered.

So far radium has found its chief use in inoperable cases and in superficial lesions. Abbe ("New York Med. Jour.," Feb. 10, 1912) says, we may suppress the short rays which burn, and yet use the deeply penetrating rays by placing a considerable amount of radium in lead which is from $\frac{1}{10}$ to 2 mm. in thickness.

Macdonald ("Brit. Med. Jour.," Dec. 9, 1911) uses for a deep growth at least 250 mg. of bromid of radium in platinum $2\frac{1}{2}$ mm. thick. He keeps the tube applied from twenty-four to forty-eight hours. In some cases he inserts the tube in the tumor and leaves it in place for forty-eight hours. A long application is not to be repeated for five or six weeks. For a superficial growth he uses radium in a glass tube every other day for a week.

It may develop that radium has decided power in preventing recurrence after operation. In some few cases of cancer radium may convert an inoperable into an operable case.

A serious bar to the extensive use of radium is its immense cost. The little there is in the world is in the hands of a few men and a few institutions. Altruistic persons in many lands are striving to give greater numbers access to the supposedly beneficent influence of that wonderful element. No process ever was so thoroughly and dramatically advertised as the radium treatment of cancer. There is a hideous cruelty in the newspaper exploitation of radium therapy, because great numbers of persons who are victims of cancer have been caused to believe that they could certainly be cured if they could gain access to radium. Such hopes cannot be realized. Any statement that an extensive cancer can *usually* or even *often* be cured by radium is a stupid mistake or a heartless deception. At the present time the real truth of the matter is being slowly and carefully studied out by earnest men who are not seeking profitable notoriety. There is little evidence at present that radium, except in certain exceptional cases, has greater curative power than the *x*-rays, and the Coolidge *x*-ray tube may remove even these exceptional cases from the radium side of the scale.

XLI. INJURIES BY ELECTRICITY

Effects Produced by Lightning.—Every year in the United States about 224 persons are killed by lightning (McAdie, as quoted in Draper's "Legal Medicine"). An individual may be struck directly or he may be shocked by the lightning having struck a nearby object. A person can be struck while in a room, but there is more danger when he is exposed, especially in the open country. To be under a single tree or under a tree at the margin of a forest during a thunder-storm is dangerous, but to be in a wood or under a hedge is reasonably safe. The oak is struck more often and the beech less often than other trees. During a thunder-storm it is not safe to stand by a chimney or fireplace, in an open doorway, or close to cattle (McAdie, Ibid.). One should not use a telephone or ring a bell during a storm. It is unwise to run, as the current of air thus created is a danger. Telegraph posts should be avoided. A pool of water is a dangerous neighbor. Horses and other animals should be given a wide berth. The victim of lightning may be killed instantly. The body may show no mark, but there are usually burns. Burns may be superficial, or a large area (as a limb) may be carbonized. Death is the fate of over one-third of those struck. Tidy ("Legal Medicine") states that out of 54 cases, 21 died and 33 recovered. Recovery may follow even when there has been severe burning. Postmortem examination may fail to reveal a lesion, but in many cases severe burns are discovered; in some there are laceration of tissue, crushing of bones, and fearful injury. Burns are especially apt to occur at the points where the current entered and emerged. The clothes are usually singed or torn, shoes are especially apt to be torn apart or

destroyed. Yet a man may be burned or killed and the clothing be undamaged, or the underclothing may be destroyed and the outer garments escape uninjured. A person's clothing may be destroyed, he may be left naked, and yet he may not be injured. Clothing may be cast far off, and in some cases is said to have utterly disappeared. The typical lightning-marks are arborescent tracings, representing the course of blood-vessels, produced by disorganization and effusion of blood as the fluid travels through it. Occasionally metal objects, such as buttons, knives, money, keys, etc., are fused, and spread as a metallic film over a considerable portion of the surface of the body. Bichat stated that in death from lightning rigor mortis does not occur. This statement is now known to be an error (see the 3 cases reported by M. Tourdes). As a rule, there are early but perhaps brief rigor mortis, retained fluidity of blood, and distention of the brain with venous blood. Putrefaction is early and rapid. A man killed by lightning may remain in the exact attitude in which he was struck dead. He may not be disfigured, his clothing may be intact, and yet, almost at a touch, he may crumble to ashes because the body was practically incinerated (see the apparently authentic cases quoted by Flammarion in "Thunder and Lightning"). In most cases killed the body shows burns. The cause of death by lightning was supposed by Hunter to be destruction of muscular contractility, and by Richardson the resolution of the blood into gases. It is asserted that some deaths are due to actual disorganization of vital structure and that others are due to shock or inhibition. Spitzka believes that death from electric shock is due to asphyxia, to paralysis of the heart with fibrillary contractions of that organ, or to a combination of these conditions. An individual struck by lightning may recover even when he is *apparently* dead. Sestier[1] collected reports of 77 persons struck by lightning; 7 of them were apparently dead for a number of hours, but finally reacted. Brouardel says in such cases the death-like state may be ascribed to inhibition, caused by a *maximum* degree of stimulus.[2] When death from lightning is not immediate, the condition may be as above outlined, the individual being apparently dead, without obvious respiration or pulse. He may be insensible, with slow and labored respiration, a weak and irregular pulse, and dilated pupils, and may remain in this condition for a few minutes or for several hours. The above condition is scarcely to be distinguished from severe concussion of the brain. Every individual suffering from the effect of lightning should have his entire body carefully examined to see if physical injures exist (fractures, wounds, burns, ecchymoses, arborescent tracings). The consequences of lightning-stroke are many and various. There may be rapid and complete recovery, gradual recovery, traumatic neurasthenia, sloughing burns, partial paralysis, which is usually recovered from (Nothnagel), but which may be permanent; hysteria, blindness, change of character, and actual insanity.

Treatment.—Do not pronounce a person dead until a thorough attempt at resuscitation has been made. Raise the head a little, draw the tongue forward. Make artificial respiration in the prone position (Schäfer's method). Occasionally tickle the epiglottis, apply external heat, massage over the heart, and, if the means are at hand and the man is apparently dead or all but dead, throw salt solution and adrenalin into a large artery and toward the heart, as advised by Crile and Dolley (see page 468). Do not give alcoholic stimulants. If the respiration is feeble, make tongue traction and employ artificial respiration. Apply the stream of a hot douche to the head, rub the limbs with mustard, put a mustard plaster over the heart and another to the back of the neck, wrap the individual in hot blankets, give

[1] Sestier, "De la Foudre," Paris, 1866. Quoted by Brouardel in his lectures upon "Death and Sudden Death."

[2] Benham's translation of Brouardel's lectures upon "Death and Sudden Death."

enemata of hot saline fluid, and strychnin hypodermatically. In some cases venesection has seemed to be of benefit. Lumbar puncture may be tried. When the individual reacts, treat any existing condition symptomatically, and treat particular physical injuries according to their character.

Effects of Artificial Currents.—Individuals may receive dangerous or fatal shocks by contact with wires carrying a powerful electric current, by contact with a dynamo, or with some metal object which has become accidentally charged by a powerful current. The shock may be from contact with both poles of a circuit (while standing on the ground and touching one pole of a "grounded" circuit); when actual contact has not occurred, but a person has been very close to a high-tension current and the current has junped an inch or several inches through the air; when a person insulated from the ground grasps the conductor with both hands (Spitzka, "Jour. Med. Soc. of New Jersey," 1909). Workmen for electric companies, pedestrians in the streets of a city which is lighted by electricity or in which trolley cars are employed, roofers, and firemen are liable to be injured by electricity. During many fires in cities live electric wires fall and charge the rails of a street-car track, the iron of a hook-and-ladder truck, water-tower, or a fire-escape. Firemen who come in contact with such charged materials are shocked. I have seen dozens of men thus shocked, but have as yet seen no fatal case. There are enormous differences in individual resistance and susceptibility. Spitzka points out that in 1 case death followed a shock of 65 volts, and others have survived shocks of many thousand volts. The amount of current the individual gets from the circuit is influenced by the tension of the current; the ground he stands on (metal floors and wet floors are most dangerous); the area of contact (limited area of contact means serious burning and less general shock, broad area means little or no burning and severe shock); the nature of the tissue (the thick palm offers more resistance than the lip, and the more callous the palm of the hand the greater the resistance), and the duration of the contact. An alternating current is decidedly more dangerous than a continuous current of equal strength. The constant current causes a shock only as the circuit is opened and closed. While the current is passing continuously there is no shock, although dreadful burns may be caused at this time. The alternating current causes rapidly repeated violent shocks. The arc light is either an alternating or a direct current. "Low tension currents with 30 to 150 alternations are more dangerous to the heart than if of more than 500 frequency. Greater frequencies, as in Tesla's currents, are practically harmless" (Spitzka, Ibid.). An artificial current acts like lightning. It may produce instant death, it may produce unconsciousness, delirium, stertorous respiration, Cheyne-Stokes breathing, or clonic spasms. Its effects can be often recovered from. Not unusually the victim is apparently dead, but subsequently recovers. D'Arsonval reports the case of a man who was apparently killed by the passage of 4500 volts. No attempt at resuscitation was made for one-half hour, and yet he recovered when artificial respiration was employed. Donnellan reports a case of recovery after the passage of 1000 volts. Slight shocks may cause temporary numbness and even motor paralysis. An electric shock frequently causes burns or ecchymoses and, occasionally, wounds. Wounds caused by electricity bleed profusely and are apt to slough. Spitzka (Ibid.) sets forth the effects of electric shock as follows:

"I. *Local Signs:* (*a*) Burns of the skin and hair. (*b*) Puncture and rupture of tissues. (*c*) Superficial necroses. (*d*) Metallic impregantion of the surface tissues. (*e*) Hemorrhages. (*f*) Edema, erythemas, 'lightning' figures.

"II. *General Effects:* (*a*) Loss of consciousness and of nerve-functions generally. (*b*) Paralyses or spasms of muscles. (*c*) Disturbances of respiration and cardiac action; high temperature.

"*Later:* Affections of the bowel activity: meteorism, constipation, albuminuria, icterus, incontinence or retention of urine, bloody urine, arterial rigor or spasms of arterioles, acute edema of various parts (joints); eye-symptoms of various kinds: blinding, conjunctivitis, keratitis, iritis, cataract, dislocation of lens, etc.; ear-symptoms: rupture of tympanic membranes, deafness, bleeding, epistaxis; thermal symptoms: usually a rise of temperature to 38° to 39° C., amnesia, neuritis, etc."

If death occurs it is due to asphyxia, to cardiac paralysis with fibrillary contractions of the heart, or to both conditions (Spitzka, "Jour. Med. Soc. of New Jersey," 1909). An *electric burn* looks like a blackened crust; it is surrounded by pale skin, and for twenty-four hours remains dry, when inflammatory oozing begins and the skin around it reddens. These burns are seldom as painful as ordinary burns, but sometimes cause severe pain, and recovery requires a long time. When inflammation begins and suppuration occurs, tissue is extensively destroyed; tendons, bones, and joints may suffer; some portions become deeply excavated, and other portions show dry adherent masses of dead and dying tissue, and a burn which was at first small may be followed by a large area of moist gangrene;[1] lack of tissue resistance, due to trophic disturbance, is largely responsible for the progress of the sloughing. Even an apparently trivial burn may be followed by extensive sloughing.

Treatment.—If a person is in contact with a live wire, the first thing to do is, if possible, to shut off the current. If it is not possible to shut off the current, catch a portion of the clothing of the victim and pull him away from the wire, but do not touch his body with the bare hand. If a pair of rubber gloves can be obtained, the subject can be moved with impunity and the wires can be safely cut. If it is not possible to drag a person away from electric wires, an individual can wrap his hands in dry woolen material and safely lift the portion of the body in contact with earth or wire, and thus break the circuit and permit removal of the body.[2] A dry cloth can be pushed between the body and the ground, and the body can then be removed from the wires. It may be possible to push the wires away by means of a dry piece of wood, or to cut them with shears which have wooden handles and which are perfectly dry, or to push or draw the body away from the wire by the employment of sticks of dry wood. Spitzka warns us to be careful in using shears "as the momentary arc formed between the separated ends may blind the rescuers." Treat the general condition in the manner set forth in the article on Lightning-stroke (see page 1472). Raise the head a little, draw the tongue forward, and tickle the epiglottis. If he does not breathe, place the patient prone and make artificial respiration by Schäfer's method. Artificial respiration may be carried out with the patient supine by Meltzer's method of tracheal insufflation or by the pulmotor (see "Report of the Commission on Resuscitation from Electric Shock," June, 1913). Always apply external heat and massage over the cardiac region. If facilities are at hand and the victim is apparently dead, inject at once adrenalin and salt solution into a large artery (see page 468). While any heart action remains there is a chance of resuscitation. When heart action and respiration are present the prognosis is good. Very severe burns may be caused. The author has dressed many electric burns with hot fomentations of salt solution during the first few days. This facilitates the separation of the sloughs and seems to aid the weakened tissues in resisting microbic invasion; after sloughs separate, the part is dressed with dry sterile gauze. Antiseptic dressings can be used from the beginning, but they often fail entirely to arrest the sloughing. Iodoform produces much irritation and

[1] See the article by N. W. Sharpe on "Peculiarities and Treatment of Electrical Injuries," in "Phila. Med. Jour.," Jan. 29, 1898.

[2] See the directions in "Med. Record," Dec. 28, 1895, from "Med. Press."

should not be employed. Ointments are very unsatisfactory. When the dressings are changed, the part should not be washed with corrosive sublimate, as this agent produces irritation; peroxid of hydrogen should be employed, followed by warm normal salt solution. Sharpe removes sloughs by applying the following mixture: 2 parts of scale pepsin, 1 part of hydrochloric acid, U. S. P., 120 parts of distilled water. This mixture is washed off after two hours with peroxid of hydrogen. The same surgeon treats necrosis of bone by injecting every few hours a 3 per cent. solution of hydrochloric acid, using every second day the pepsin solution, and when necrotic areas come away, packing with gauze. When repair begins, the raw surface should be covered with silver-foil. Skin-grafting by Reverdin's method or Thiersch's method is rarely successful. In some regions it is possible to slide a large flap in place to cover a raw area which will not heal. In a very severe case amputation or resection may be necessary.

In New York, Pennsylvania, New Jersey, and several other states electricity is employed to execute criminals convicted of capital offenses. The infliction of death by electricity is popularly spoken of as *electrocution*. It is beyond doubt, in the words of my colleague, Professor Spitzka, "the most humane method of executing criminals." The first electrocution in New York was in Auburn Prison in 1890, and since then over 100 criminals have been executed by electricity in New York state alone. Dr. Spitzka has witnessed 36 electrocutions and made autopsies on 27 of the victims ("Jour. Med. Soc. of New Jersey," 1909). The apparatus used is "an alternating dynamo capable of generating 2000 volts, a 'death-chair' with adjustable head-rest, binding straps, and adjustable electrodes. (At Trenton a 2400-volt current is taken from the public service wire and lowered to the desired tension by a rheostat.) The notch to control the current is in the death-chamber and the dynamo is in another apartment, communication being had by electric signals. The prisoner (usually without fetters) walks in when everything is ready and sits down in the chair, and his arms, legs, head, and chest are strapped to the chair. An electrode moist with salt solution is fastened to the head and another to the bare calf of the leg. The head need not be shaved.

"The application of the current is usually as follows: The contact is made with a high potential—1800 volts—for five to seven seconds, reduced to 250 volts until a half-minute has elapsed; raised to high voltage for three to five seconds; again reduced to low voltage until one minute has elapsed, when it is again raised to the high voltage for a few seconds, and the contact is broken. The ammeter usually shows that from 7 to 10 amperes have passed through the criminal's body.

"A second or even a third brief contact is sometimes made, partly as a precautionary measure, but more to completely abolish reflexes in the dead body.

"The time consumed by the strapping-in process is usually about forty-five seconds and the first contact is made a few seconds later. In all, about sixty to seventy seconds elapse from the moment the convict leaves his cell until he is shocked to death" (Spitzka, Ibid.).

After electrocution the temperature of the body rises and may reach 129.5° F. Dr. Spitzka finds that after removing the brain the temperature in the vertebral canal is often over 120° F. The brain shows capillary hemorrhages, arterial anemia, and venous congestion. In some of Spitzka's cases sections of the pons, oblongata, and spinal cord showed areas resembling gaseous emphysema, which were perhaps caused by "electrolytic liberation of gas."

In electrocution there is no pain, consciousness is at once abolished, death is certain, and resuscitation is impossible. The lurid stories about criminals being killed by the necropsy and not by the electric current are nonsense.

INDEX

Stelwagon's Diseases of the Skin

A Treatise on Diseases of the Skin. By HENRY W. STELWAGON, M. D., PH. D., Professor of Dermatology in the Jefferson Medical College, Philadelphia. Octavo of 1250 pages, with 331 text-cuts and 33 plates. Cloth, $6.00 net; Half Morocco, $7.50 net.

JUST READY—THE NEW (7th) EDITION

There are two features in Dr. Stelwagon's work that stand out above all the others: The special emphasis given the two practical phases of the subject—*diagnosis* and *treatment;* and the *wealth of illustrations.* These latter are of real value. They teach you diagnosis as no description can. Many of these illustrations are *in colors.*

Over 75 pages of the work are devoted to *syphilis*, giving you the Wassermann test, the salvarsan ("606") treatment, and all the newest advances. *Pellagra*, tropical affections, *hookworm disease*, Oriental sore, ringworm, impetigo contagiosa—all those diseases being so widely discussed to-day.

George T. Elliot, M. D., *Professor of Dermatology, Cornell University.*

"It is a book that I recommend to my class at Cornell, because for conservative judgment, for accurate observation, and for a thorough appreciation of the essential position of dermatology, I think it holds first place."

Schamberg's Diseases *of the* Skin *and* Eruptive Fevers

Diseases of the Skin and the Eruptive Fevers. By JAY F. SCHAMBERG, M. D., Professor of Dermatology and the Infectious Eruptive Diseases, Philadelphia Polyclinic. Octavo of 573 pages, illustrated. Cloth, $3.00 net.

THE NEW (2d) EDITION

"The acute eruptive fevers constitute a valuable contribution, the statements made emanating from one who has studied these diseases in a practical and thorough manner from the standpoint of cutaneous medicine. . . . The views expressed on all topics are conservative, safe to follow, and practical, and are well abreast of the knowledge of the present time, both as to general and special pathology, etiology, and treatment."—*American Journal of Medical Sciences.*

Norris'
Gonorrhea in Women

Gonorrhea in Women. By CHARLES C. NORRIS, M. D., Instructor in Gynecology, University of Pennsylvania, with an Introduction by JOHN G. CLARK, M. D., Professor of Gynecology, University of Pennsylvania. Large octavo of 520 pages, illustrated. Cloth, $6.00 net.

A CLASSIC

Dr. Norris here presents a work that is destined to take high place among publications on this subject. He has done his work thoroughly. He has searched the important literature very carefully, over 2300 references being utilized. This, coupled with Dr. Norris' long experience, gives his work the stamp of authority. The chapter on serum and vaccine therapy and organotherapy is particularly valuable because it expresses the newest advances. Every phase of the subject is considered : History, bacteriology, pathology, sociology, prophylaxis, treatment (operative and medicinal), gonorrhea during pregnancy, parturition and the puerperium, diffuse gonorrheal peritonitis, and all other phases. Further, Dr. Norris considers the rare varieties of gonorrhea occurring in men, women, and children. The text is illustrated.

Sharp's
Ophthalmology for Veterinarians

Ophthalmology for Veterinarians. By WALTER N. SHARP, M. D., Professor of Ophthalmology in the Indiana Veterinary College. 12mo of 210 pages, illustrated. Cloth, $2.00 net.

ILLUSTRATED

This new work covers a much neglected but important field of veterinary practice. Dr. Sharp has presented his subject in a concise, crisp way, so that you can pick up this book and get to "the point" quickly. He first gives you the anatomy of the eye, then examination, followed by the various diseases, including injuries, parasites, errors of refraction, and medicines used in ophthalmic therapeutics. The text is illustrated.

Barnhill and Wales' Modern Otology

A Text-Book of Modern Otology. By John F. Barnhill, M. D., Professor of Otology, Laryngology, and Rhinology, and Earnest de W. Wales, M. D., Associate Professor of Otology, Laryngology, and Rhinology, Indiana University School of Medicine, Indianapolis. Octavo of 598 pages, with 314 original illustrations. Cloth, $5.50 net; Half Morocco, $7.00 net.

THE NEW (2d) EDITION

The authors, in writing this work, kept ever in mind the needs of the physician engaged in general practice. It represents the results of personal experience as practitioners and teachers, influenced by the instruction given by such authorities as Sheppard, Dundas Grant, Percy Jakins, Jansen, and Alt. Much space is devoted to prophylaxis, diagnosis, and treatment, both *medical and surgical*. There is a special chapter on *the bacteriology of ear affections*—a feature not to be found in any other work on otology. Great pains have been taken with the illustrations, in order to have them as practical and as helpful as possible, and at the same time highly artistic. A large number represent the best work of Mr. H. F. Aitken.

PERSONAL AND PRESS OPINIONS

Frank Allport, M. D.

Professor of Otology, Northwestern University, Chicago.

"I regard it as one of the best books in the English language on this subject. The pictures are especially good, particularly as they are practically all original and not the old reproduced pictures so frequently seen."

C. C. Stephenson, M. D.

Professor of Ophthalmology and Otology, College of Physicians and Surgeons, Little Rock Arkansas.

"To my mind there is no work on modern otology that can for a moment compare with 'Barnhill and Wales.'"

Journal American Medical Association

"Its teaching is sound throughout and up to date. The strongest chapters are those on suppuration of the middle ear and the mastoid cells, and the intracranial complications of ear disease."

GET THE BEST **American** THE NEW STANDARD

Illustrated Dictionary

New (7th) Edition—5000 Sold in Two Months

The American Illustrated Medical Dictionary. A new and complete dictionary of the terms used in Medicine, Surgery, Dentistry, Pharmacy, Chemistry, Veterinary Science, Nursing, and kindred branches; with over 100 new and elaborate tables and many illustrations. By W. A. Newman Dorland, M.D., Editor of "The American Pocket Medical Dictionary." Large octavo, with 1107 pages, bound in full flexible leather. Price, $4.50 net; with thumb index, $5.00 net.

KEY TO CAPITALIZATION AND PRONUNCIATION—ALL THE NEW WORDS

This dictionary is the "new standard." It defines hundreds of the newest terms not defined in any other dictionary—bar none. These terms are live, active words, taken right from modern medical literature.

Howard A. Kelly, M. D.,
Professor of Gynecologic Surgery, Johns Hopkins University, Baltimore

"Dr. Dorland's Dictionary is admirable. It is so well gotten up and of such convenient size. No errors have been found in my use of it."

Theobald's Prevalent Eye Diseases

Prevalent Diseases of the Eye. By Samuel Theobald, M. D., Clinical Professor of Ophthalmology and Otology, Johns Hopkins University. Octavo of 550 pages, with 219 text-cuts and several colored plates. Cloth, $4.50 net; Half Morocco, $6.00 net.

THE PRACTITIONER'S OPHTHALMOLOGY

With few exceptions all the works on diseases of the eye, although written ostensibly for the general practitioner, are in reality adapted only to the specialist; but Dr. Theobald in his book has described very clearly and in detail those conditions, the diagnosis and treatment of which come within the province of the general practitioner. The therapeutic suggestions are concise, unequivocal, and specific. It is the one work on the Eye written particularly for the general practitioner.

Charles A. Oliver, M.D.,
Clinical Professor of Ophthalmology, Woman's Medical College of Pennsylvania.

"I feel I can conscientiously recommend it, not only to the general physician and medical student, for whom it is primarily written, but also to the experienced ophthalmologist. Most surely Dr. Theobald has accomplished his purpose."

Haab and DeSchweinitz's External Diseases *of the* Eye

Atlas and Epitome of External Diseases of the Eye. By DR. O. HAAB, of Zürich. Edited, with additions, by G. E. DESCHWEINITZ, M. D., Professor of Ophthalmology, University of Pennsylvania. With 101 colored illustrations on 46 lithographic plates and 244 pages of text. Cloth, $3.00 net. *In Saunders' Hand-Atlas Series.*

THE NEW (3d) EDITION

Conditions attending diseases of the external eye, which are often so complicated, have probably never been more clearly and comprehensively expounded than in the forelying work, in which the pictorial most happily supplements the verbal description. The price of the book is remarkably low.

The Medical Record, New York

"The work is excellently suited to the student of ophthalmology and to the practising physician. It cannot fail to attain a well-deserved popularity."

Haab and DeSchweinitz's Ophthalmoscopy

Atlas and Epitome of Ophthalmoscopy and Ophthalmoscopic Diagnosis. By Dr. O. HAAB, of Zürich. Edited, with additions, by G. E. DESCHWEINITZ, M. D., Professor of Ophthalmology, University of Pennsylvania. With 152 colored lithographic illustrations and 92 pages of text. Cloth, $3.00 net. *In Saunders' Hand-Atlas Series.*

THE NEW (2d) EDITION

The great value of Prof. Haab's Atlas of Ophthalmoscopy and Ophthalmoscopic Diagnosis has been fully established and entirely justified an English translation. Not only is the student made acquainted with carefully prepared ophthalmoscopic drawings done into well-executed lithographs of the most important fundus changes, but, in many instances, plates of the microscopic lesions are added. The whole furnishes a manual of the greatest possible service.

The Lancet, London

"We recommend it as a work that should be in the ophthalmic wards or in the library of every hospital into which ophthalmic cases are received."

Gradle's
Nose, Pharynx, and Ear

Diseases of the Nose, Pharynx, and Ear. By HENRY GRADLE, M.D., late Professor of Ophthalmology and Otology, Northwestern University Medical School, Chicago. Octavo of 547 pages, illustrated, including two full-page plates in colors. Cloth, $3.50 net.

INCLUDING TOPOGRAPHIC ANATOMY

This volume presents diseases of the Nose, Pharynx, and Ear as the author has seen them during an experience of nearly twenty-five years. In it are answered in detail those questions regarding the course and outcome of diseases which cause the less experienced observer the most anxiety in an individual case. Topographic anatomy has been accorded liberal space.

Pennsylvania Medical Journal

"This is the most practical volume on the nose, pharynx, and ear that has appeared recently. . . . It is exactly what the less experienced observer needs, as it avoids the confusion incident to a categorical statement of everybody's opinion."

Kyle's
Diseases of Nose *and* Throat

Diseases of the Nose and Throat. By D. BRADEN KYLE, M. D., Professor of Laryngology in the Jefferson Medical College, Philadelphia. Octavo, 797 pages; with 219 illustrations, 26 in colors. Cloth, $4.00 net; Half Morocco, $5.50 net.

THE NEW (4th) EDITION

Four large editions of this excellent work fully testify to its practical value. In this edition the author has revised the text thoroughly, bringing it absolutely down to date. With the practical purpose of the book in mind, extended consideration has been given to treatment, each disease being considered in full, and definite courses being laid down to meet special conditions and symptoms.

Pennsylvania Medical Journal

"Dr. Kyle's crisp, terse diction has enabled the inclusion of all needful nose and throat knowledge in this book. The practical man, be he special or general, will not search in vain for anything he needs."

Ogden on the Urine

Clinical Examination of Urine and Urinary Diagnosis. A Clinical Guide for the Use of Practitioners and Students of Medicine and Surgery. By J. Bergen Ogden, M. D., Medical Chemist to the Metropolitan Life Insurance Company, New York. Octavo, 418 pages, 54 text illustrations, and a number of colored plates. Cloth, $3.00 net.

THE NEW (3d) EDITION

In this edition the work has been brought absolutely down to the present day. Urinary examinations for purposes of life insurance have been incorporated, because a large number of practitioners are often called upon to make such analyses. Special attention has been paid to diagnosis by the character of the urine, the diagnosis of diseases of the kidneys and urinary passages ; an enumeration of the prominent clinical symptoms of each disease ; and the peculiarities of the urine in certain general diseases.

The Lancet, London

"We consider this manual to have been well compiled ; and the author's own experience, so clearly stated, renders the volume a useful one both for study and reference."

Pilcher's Practical Cystoscopy

Practical Cystoscopy. By Paul M. Pilcher, M. D., Consulting Surgeon to the Eastern Long Island Hospital. Octavo of 398 pages, with 233 illustrations, 29 in colors. Cloth, $5.50 net.

DIAGNOSIS AND TREATMENT

Cystoscopy is to-day the most practical manner of diagnosing and treating diseases of the bladder, ureters, kidneys, and prostate. To be properly equipped, therefore, you must have at your instant command the information this book gives you. It explains away all difficulty, telling you *why* you do not see something when something *is* there to see, and telling you *how* to see it. All theory has been uncompromisingly eliminated, devoting every line to practical, needed-every-day facts, telling you how and when to use the cystoscope and catheter—telling you in a way to make you *know*. The work is complete in every detail.

Bransford Lewis, M. D., *St. Louis University.*

"I am very much pleased with Dr. Pilcher's 'Practical Cystoscopy.' I think it is the best in the English language now."—*April 27, 1911.*

Goepp's
Dental State Boards

Dental State Board Questions and Answers.—By R. MAX GOEPP, M. D., author "Medical State Board Questions and Answers." Octavo of 428 pages. Cloth, $2.75 net.

COMPLETE AND ACCURATE

This new work is along the same practical lines as Dr. Goepp's successful work on Medical State Boards. The questions included have been gathered from reliable sources, and embrace all those likely to be asked in any State Board examination in any State. They have been arranged and classified in a way that makes for a rapid résumé of every branch of dental practice, and the answers are couched in language unusually explicit—concise, definite, accurate.

The practicing dentist, also, will find here a work of great value—a work covering the entire range of dentistry and extremely well adapted for quick reference.

Haab *and* deSchweinitz's
Operative Ophthalmology

Atlas and Epitome of Operative Ophthalmology. By DR. O. HAAB, of Zurich. Edited, with additions, by G. E. DE SCHWEINITZ, M. D., Professor of Ophthalmology in the University of Pennsylvania. With 30 colored lithographic plates, 154 text-cuts, and 375 pages of text. *In Saunders' Hand-Atlas Series.* Cloth, $3.50 net.

Dr. Haab's Atlas of Operative Ophthalmology will be found as beautiful and as practical as his two former atlases. The work represents the author's thirty years' experience in eye work. The various operative interventions are described with all the precision and clearness that such an experience brings. Recognizing the fact that mere verbal descriptions are frequently insufficient to give a clear idea of operative procedures, Dr. Haab has taken particular care to illustrate plainly the different parts of the operations.

Johns Hopkins Hospital Bulletin

"The descriptions of the various operations are so clear and full that the volume can well hold place with more pretentious text-books."

Greene *and* Brooks' Genito-Urinary Diseases

Diseases of the Genito-Urinary Organs and the Kidney. By ROBERT H. GREENE, M. D., Professor of Genito-Urinary Surgery at Fordham University; and HARLOW BROOKS, M. D., Assistant Professor of Clinical Medicine, University and Bellevue Hospital Medical School. Octavo of 639 pages, illustrated. Cloth, $5.00 net; Half Morocco, $6.50 net.

THE NEW (3d) EDITION

This new work presents *both the medical and surgical sides.* Designed as a work of quick reference, it has been written in a clear, condensed style, so that the information can be readily grasped and retained. *Kidney diseases* are very elaborately detailed.

New York Medical Journal

"As a whole the book is one of the most satisfactory and useful works on genito-urinary diseases now extant, and will undoubtedly be popular among practitioners and students."

Gleason on Nose, Throat, and Ear

A Manual of Diseases of the Nose, Throat, and Ear. By E. BALDWIN GLEASON, M. D., LL. D., Clinical Professor of Otology, Medico-Chirurgical College, Philadelphia. 12mo of 556 pages, profusely illustrated. Flexible leather, $2.50 net.

THE NEW (2d) EDITION

Methods of treatment have been simplified as much as possible, so that in most instances only those methods, drugs, and operations have been advised which have proved beneficial. A valuable feature consists of the collection of formulas.

American Journal of the Medical Sciences

"For the practitioner who wishes a reliable guide in laryngology and otology there are few books which can be more heartily commended."

American Text-Book of Genito-Urinary Diseases, Syphilis, and Diseases of the Skin. Edited by L. BOLTON BANGS, M. D., and W. A. HARDAWAY, M. D. Octavo, 1229 pages, 300 engravings, 20 colored plates. Cloth, $7.00 net.

Holland's Medical Chemistry and Toxicology

A Text-Book of Medical Chemistry and Toxicology. By James W. Holland, M. D., Professor of Medical Chemistry and Toxicology, and Dean, Jefferson Medical College, Philadelphia. Octavo of 675 pages, fully illustrated. Cloth, $3.00 net.

THE NEW (3d) EDITION

Dr. Holland's work is an entirely new one, and is based on his forty years' practical experience in teaching chemistry and medicine. It has been subjected to a thorough revision, and enlarged to the extent of some sixty pages. The additions to be specially noted are those relating to the electronic theory, chemical equilibrium, Kjeldahl's method for determining nitrogen, chemistry of foods and their changes in the body, synthesis of proteins, and the latest improvements in urinary tests. More space is given to toxicology than in any other text-book on chemistry.

American Medicine

"Its statements are clear and terse; its illustrations well chosen; its development logical, systematic, and comparatively easy to follow. . . . We heartily commend the work."

Ivy's Applied Anatomy and Oral Surgery for Dental Students

Applied Anatomy and Oral Surgery for Dental Students. By Robert H. Ivy, M.D., D.D.S., Assistant Oral Surgeon to the Philadelphia General Hospital. 12mo of 280 pages, illustrated. Cloth, $1.50 net.

FOR DENTAL STUDENTS

This work is just what dental students have long wanted—a concise, practical work on applied anatomy and oral surgery, written with their needs solely in mind. No one could be better fitted for this task than Dr. Ivy, who is a graduate in both dentistry and medicine. Having gone through the dental school, he knows precisely the dental student's needs and just how to meet them. His medical training assures you that his anatomy is accurate and his technic modern. The text is well illustrated with pictures that you will find extremely helpful.

H. P. Kuhn, M.D., *Western Dental College, Kansas City.*

"I am delighted with this compact little treatise. It seems to me just to fill the bill."

American Pocket Dictionary — New (8th) Edition

The American Pocket Medical Dictionary. Edited by W. A. Newman Dorland, M. D., Editor "American Illustrated Medical Dictionary." Containing the pronunciation and definition of the principal words used in medicine and kindred sciences. 677 pages. Flexible leather, with gold edges, $1.00 net; with thumb index, $1.25 net.

James W. Holland, M. D.,

Professor of Medical Chemistry and Toxicology, and Dean, Jefferson Medical College, Philadelphia,

"I am struck at once with admiration at the compact size and attractive exterior. I can recommend it to our students without reserve."

Stelwagon's Essentials of Skin — 7th Edition

Essentials of Diseases of the Skin. By Henry W. Stelwagon, M. D., Ph.D., Professor of Dermatology in the Jefferson Medical College, Philadelphia. Post-octavo of 291 pages, with 72 text-illustrations and 8 plates. Cloth, $1.00 net. *In Saunders' Question-Compend Series.*

The Medical News

"In line with our present knowledge of diseases of the skin. . . . Continues to maintain the high standard of excellence for which these question compends have been noted."

Wolff's Medical Chemistry — New (7th) Edition

Essentials of Medical Chemistry, Organic and Inorganic. Containing also Questions on Medical Physics, Chemical Physiology, Analytical Processes, Urinalysis, and Toxicology. By Lawrence Wolff, M. D., Late Demonstrator of Chemistry, Jefferson Medical College. Revised by A. Ferree Witmer, Ph. G., M. D., Formerly Assistant Demonstrator of Physiology, University of Pennsylvania. Post-octavo of 222 pages. Cloth, $1.00 net. *In Saunders' Question-Compend Series.*

Martin's Minor Surgery, Bandaging, and the Venereal Diseases — Second Edition, Revised

Essentials of Minor Surgery, Bandaging, and Venereal Diseases. By Edward Martin, A. M., M. D., Professor of Clinical Surgery, University of Pennsylvania, etc. Post-octavo, 166 pages, with 78 illustrations. Cloth, $1.00 net. *In Saunders' Question-Compend Series.*

Vecki's Sexual Impotence — New (4th) Edition

Sexual Impotence. By Victor G. Vecki, M. D., Consulting Genito-Urinary Surgeon to Mt. Zion Hospital, San Francisco. 12mo of 400 pages. Cloth, $2.25 net.

Johns Hopkins Hospital Bulletin

"A scientific treatise upon an important and much neglected subject. . . . The treatment of impotence in general and of sexual neurasthenia is discriminating and judicious."

Wells' Chemical Pathology

Chemical Pathology. Being a discussion of General Pathology from the Standpoint of the Chemical Processes Involved. By H. Gideon Wells, Ph. D., M. D., Assistant Professor of Pathology in the University of Chicago. Octavo of 549 pages. Cloth, $3.25 net; Half Morocco, $4.75 net.

Wm. H. Welch, M. D., *Professor of Pathology, Johns Hopkins University.*

"The work fills a real need in the English literature of a very important subject, and I shall be glad to recommend it to my students."

Saxe's Urinalysis

The New (2d) Edition

Examination of the Urine. By G. A. De Santos Saxe, M. D., formerly Instructor in Genito-Urinary Surgery, New York Post-graduate Medical School and Hospital. 12mo of 448 pages, fully illustrated. Cloth, $1.75 net.

Francis Carter Wood, M. D., *Adjunct Professor of Clinical Pathology, Columbia University.*

"It seems to me to be one of the best of the smaller works on this subject; it is, indeed, better than a good many of the larger ones."

deSchweinitz and Randall on the Eye, Ear, Nose, and Throat

American Text-Book of Diseases of the Eye, Ear, Nose, and Throat. Edited by G. E. de Schweinitz, M.D., and B. Alexander Randall, M.D. Imperial octavo, 1251 pages, with 766 illustrations, 59 of them in colors. Cloth, $7.00 net; Half Morocco, $8.50 net.

Grünwald and Grayson on the Larynx

Atlas and Epitome of Diseases of the Larynx. By Dr. L. Grünwald, of Munich. Edited, with additions, by Charles P. Grayson, M.D., University of Pennsylvania. With 107 colored figures on 44 plates, 25 text-cuts, and 103 pages of text. Cloth, $2.50 net. *In Saunders' Hand-Atlas Series.*

Mracek and Stelwagon's Atlas of Skin

Second Edition

Atlas and Epitome of Diseases of the Skin. By Prof. Dr. Franz Mracek, of Vienna. Edited, with additions, by Henry W. Stelwagon, M.D., Jefferson Medical College. With 77 colored plates, 50 half-tone illustrations, and 280 pages of text. *In Saunders' Hand-Atlas Series.* Cloth, $4.00 net.

de Schweinitz and Holloway on Pulsating Exophthalmos

Pulsating Exophthalmos. An analysis of sixty-nine cases not previously analyzed. By George E. deSchweinitz, M. D., and Thomas B. Holloway, M. D. Octavo of 125 pages. Cloth, $2.00 net.

This monograph consists of an analysis of sixty-nine cases of this affection not previously analyzed. The therapeutic measures, surgical and otherwise, which have been employed are compared, and an endeavor has been made to determine from these analyses which procedures seem likely to prove of the greatest value. It is the most valuable contribution to ophthalmic literature within recent years.

British Medical Journal

"The book deals very thoroughly with the whole subject and in it the most complete account of the disease will be found."

Jackson on the Eye — The New (2d) Edition

A Manual of the Diagnosis and Treatment of Diseases of the Eye. By Edward Jackson, A. M., M. D., Professor of Ophthalmology, University of Colorado. 12mo volume of 615 pages, with 184 beautiful illustrations. Cloth, $2.50 net.

The Medical Record, New York

"It is truly an admirable work. . . . Written in a clear, concise manner, it bears evidence of the author's comprehensive grasp of the subject. The term 'multum in parvo' is an appropriate one to apply to this work."

Grant on Face, Mouth, and Jaws

A Text-Book of the Surgical Principles and Surgical Diseases of the Face, Mouth, and Jaws. For Dental Students. By H. Horace Grant, A. M., M. D., Professor of Surgery and of Clinical Surgery, Hospital College of Medicine, Louisville. Octavo of 231 pages, with 68 illustrations. Cloth, $2.50 net.

Preiswerk and Warren's Dentistry

Atlas and Epitome of Dentistry. By Prof. G. Preiswerk, of Basil. Edited, with additions, by George W. Warren, D.D.S., Professor of Operative Dentistry, Pennsylvania College of Dental Surgery, Philadelphia. With 44 lithographic plates, 152 text-cuts, and 343 pages of text. Cloth, $3.50 net. *In Saunders' Atlas Series.*

Friedrich and Curtis on Nose, Larynx, and Ear

Rhinology, Laryngology, and Otology, and Their Significance in General Medicine. By Dr. E. P. Friedrich, of Leipzig. Edited by H. Holbrook Curtis, M. D., Consulting Surgeon to the New York Nose and Throat Hospital. Octavo volume of 350 pages. Cloth, $2.50 net.

Wolf's Examination of Urine

A Laboratory Handbook of Physiologic Chemistry and Urine-examination. By Charles G. L. Wolf, M. D., Instructor in Physiologic Chemistry, Cornell University Medical College, New York. 12mo volume of 204 pages, fully illustrated. Cloth, $1.25 net.

British Medical Journal

"The methods of examining the urine are very fully described, and there are at the end of the book some extensive tables drawn up to assist in urinary diagnosis."

Jackson's Essentials of Eye

Third Revised Edition

Essentials of Refraction and of Diseases of the Eye. By Edward Jackson, A. M., M. D., Emeritus Professor of Diseases of the Eye, Philadelphia Polyclinic. Post-octavo of 261 pages, 82 illustrations. Cloth, $1.00 net. *In Saunders' Question-Compend Series.*

Johns Hopkins Hospital Bulletin

"The entire ground is covered, and the points that most need careful elucidation are made clear and easy."

Gleason's Nose and Throat

Fourth Edition, Revised

Essentials of Diseases of the Nose and Throat. By E. B. Gleason, S. B., M. D., Clinical Professor of Otology, Medico-Chirurgical College, Philadelphia, etc. Post-octavo, 241 pages, 112 illustrations. Cloth, $1.00 net. *In Saunders' Question Compends.*

The Lancet, London

"The careful description which is given of the various procedures would be sufficient to enable most people of average intelligence and of slight anatomical knowledge to make a very good attempt at laryngoscopy."

Gleason's Diseases of the Ear

Third Edition, Revised
